Radioactivity and Health A History

J. Newell Stannard

Professor Emeritus
School of Medicine and Dentistry
University of Rochester

Adjunct Professor
School of Medicine
University of California, San Diego

October 1988

Edited by Raymond W. Baalman, Jr.
Pacific Northwest Laboratory

Prepared for the U.S. Department of Energy,
Office of Health and Environmental Research
under Contract DE-AC06-76RLO 1830

Pacific Northwest Laboratory
Operated for the U.S. Department of Energy
by Battelle Memorial Institute

REPRODUCED BY:

Radioactivity and Health: A History

*To disseminate knowledge is to
disseminate prosperity—I mean
general prosperity not individual
riches—and with prosperity
disappears the greater part of
the evil which is our heritage
from darker times.*

Alfred Nobel

CONTENTS

List of Figures	XXI
List of Tables	XXXI
Foreword	XXXVII
Preface	XLI
Preface to Section I Naturally Occurring Radioactive Elements	1
Chapter 1 First It Was Radium	15
Outline	15
Capsule Chronology	17
Overview	21
I. Introduction	21
II. The Early Decades	22
III. Luminous Dial Painters, Radium Patients, etc.: The First Decade of Enlightenment	23
IV. The Decade of the 1930s: Quantitation, Therapy, and Metabolism	26
A. The Transition	26
B. Measurement in Vivo	27
C. Approaches to Therapy	29
D. Distribution, Excretion, and Retention of Radium	30
V. Radium Research During World War II	32
A. Introductory Considerations	32
B. The Chicago Work on Radium-226	33
C. Experiments at Rochester with Radium-226	37
D. Radium Research at Massachusetts Institute of Technology- Harvard-Massachusetts General Hospital During World War II	41
E. Other Studies	42
VI. Postwar Radium Research	43
A. General Comments	43
B. Postwar Radium Research at the Massachusetts Institute of Technology	44
C. Postwar Radium Research at Chicago (Argonne National Laboratory/Argonne Cancer Research Hospital)	52
D. Other Postwar Radium Research	61
VII. Radium-224	66
A. The Population	67
B. The Dosages	68
C. The Effects	69
D. On the Effect of Dose Protraction	69
E. Comment	69
VIII. Summary and Commentary	71
References	72
Chapter 2 Uranium	79
Outline	79
Capsule Chronology	81
Overview	83
I. Introduction	84
II. World War II	85
A. General Organization	85

VIII Contents

B.	The Initial Approach to the Toxicology	88
C.	The Initial Toxicology Results	89
D.	Biochemical Aspects	91
E.	Pathology	95
III.	Postwar Animal Studies	96
A.	The Rochester Inhalation Experiment	96
B.	The Oak Ridge and Related Experiments Using Animals	98
C.	Other Postwar Animal Experiments	98
IV.	Data on Man	98
A.	Occupational Exposure	98
B.	Planned Administrations	100
V.	The Higher-Specific-Activity Isotopes and Enriched Uranium	102
VI.	Postscript	104
VII.	Summary and Commentary	105
	References	107

Chapter 3 Radon and Radon Decay Products: The Saga of the Uranium Miners 113

	Outline	113
	Capsule Chronology	115
	Overview	119
I.	Introduction	120
II.	The Earlier Years in the Mines	122
A.	Mysterious Mountains	122
B.	Identification of Lung Cancer	123
C.	Forays at Causation	124
III.	The Middle Years in the Mines	125
A.	Accumulating Information on the Miners	126
B.	Closing in on Radon	128
C.	The First Standard	130
IV.	The Later Years in the Mines and Mills	131
A.	The World-War-II Years	131
B.	New Populations to Study	133
V.	Dosimetric Problems	135
A.	The Role of the Daughters	136
B.	The Dose to Lung	139
C.	Modeling	140
D.	The Need for a New Measure—Genesis of the Working Level	141
E.	Methods of Measurement	146
VI.	The Epidemiologic Studies in the Postwar Era	147
A.	The U.S. Uranium Miners	147
B.	Why Did it Happen Here?	154
C.	Other Uranium Mines	156
D.	Other Miners	157
E.	Commentary on the Epidemiologic Results	158
VII.	The Spas and Therapeutic Mines	160
A.	The Spas and Therapeutic Galleries in Europe	160
B.	Spas and Therapeutic Mines in the United States	161
C.	The Radon Levels Involved	164
D.	The Possibility of Effects	165
VIII.	Experimental Animal Research	166
A.	Early Studies	166
B.	The Post-World-War-II Years	167
IX.	Research on Control of the Mine Environment	173
A.	Instrument Design	173

B. Aerosol Research	174
C. Respirators	174
D. Bioassay	174
X. Environmental and Population Exposures to Radon and Radon Daughters	174
A. Exposures Indoors	175
B. Exposures Outdoors	179
C. Amounts in Water	180
D. Significance	180
E. Recent Events	180
XI. Summary and Commentary	181
Note 1	182
Note 2	184
References	186

Chapter 4 Polonium and Thorium

Outline	195
Capsule Chronology	197
Overview	201
Prologue	202
Part A. Polonium	202
I. Introduction	202
II. Early Research	204
III. Polonium Research During World War II	205
A. The Setting	205
B. Distribution and Excretion	206
C. Toxicity of Polonium	214
IV. Research on Distribution, Excretion, and Effects of Polonium in the Post-World-War-II Era	215
A. Introduction	215
B. Solution Chemistry and Radiocolloids	216
C. Distribution and Excretion	219
D. Effects	221
E. Work Abroad on Distribution, Excretion, and Effects of Polonium	228
V. Polonium in the Environment, Especially in Tobacco	229
A. Introduction	229
B. Natural Occurrence of Polonium	230
C. Polonium in Tobacco	232
Part B. Thorium	234
I. Introduction	234
II. The Setting and the Problems	235
III. Natural Thorium	238
A. Is There Such a Thing?	238
B. Chemical Toxicology of Long-Lived Thorium	239
C. A World-War-II False Alarm	241
IV. Distribution and Excretion of Thorium Isotopes	241
A. Animal Studies	241
B. Distribution and Excretion of Thorium Isotopes in Man	247
V. Effects of Thorium-Series Isotopes	252
A. The Thorotrast Saga	252
B. The Effects at Tracer Levels and of the Shorter-Lived Isotopes	257
C. Thoron	261

X Contents

VI. Summary and Commentary	262
A. Polonium	262
B. Thorium	263
Note 1	264
Note 2	265
References	267
Preface to Section II The Manmade Radioisotopes	275
Chapter 5 The Early Days of Manmade Radioisotopes	279
Outline	279
Capsule Chronology	281
Overview	283
I. Introduction	283
II. Preparing the Way	284
III. Manmade Radioisotopes Enter the Picture	285
IV. Overtones for Radiation Toxicology	289
V. Summary and Commentary	292
References	293
General References	293
Chapter 6 New Dimension Number One— The Fission Products; 1939-1950	295
Outline	295
Capsule Chronology	297
Overview	299
I. The Problem	299
II. The Fission Products	300
III. Tracer Studies at Berkeley	302
A. The Modus Operandi	302
B. The Results	304
C. Postlude at Berkeley	312
IV. Fission Product Research at Chicago	312
A. The Modus Operandi	312
B. Results	314
C. The Chicago Toxicity Laboratory	322
D. Postlude at Chicago	322
V. Projects "Peppermint" and "Gabriel"	323
VI. Work in Other U.S. Laboratories	324
VII. Work in the United Kingdom	324
VIII. Summary and Commentary	325
References	326
Chapter 7 New Dimension Number Two—Plutonium and the Transplutonic Elements (The Actinides); 1940-1950	331
Outline	331
Capsule Chronology	333
Overview	335
I. The Problem	336
II. The Actinide Elements	337
III. The Metabolism of Plutonium	340
A. Radiochemical Studies in Animals	340
B. Autoradiographic Studies	348
C. Metabolism of Plutonium in Man	350

IV. Toxicology of Plutonium	356
A. Acute Effects	356
B. Long-Term Toxicity of Plutonium	363
V. Wartime Biomedical Work with the Transplutonic and Related Actinide Elements	369
A. General Considerations	369
B. Metabolism	369
C. Reasons for Interest in the Transplutonium Elements	371
VI. Summary and Commentary	371
References	372
Chapter 8 Post-World-War-II Research on the Actinides and Fission Products	377
Outline	377
Capsule Chronology	381
Overview	385
I. Part of a Golden Era	386
II. Extensions and Consummations	386
A. Argonne National Laboratory	387
B. University of California at Berkeley	399
III. New Projects: The King-Sized Experiments	409
A. Background	409
B. The University of Utah Beagle Project	409
C. The Davis Beagle Project	430
D. The Lovelace Project	432
IV. Almost New Projects: Hanford and Los Alamos	434
A. The Hanford Biology Operations	434
B. Los Alamos Scientific Laboratory	450
V. Other U.S. Work	461
A. Colorado State University	461
B. New York University Institute of Environmental Sciences	463
C. Oak Ridge Institute of Nuclear Studies and University of Tennessee	463
D. University of Rochester	464
E. Other Laboratories and Organizations	465
VI. Work Abroad	469
VII. The Transplutonic Elements	470
A. Introductory Considerations	470
B. Behavior in the Body (Metabolism)	472
C. Toxicity	478
VIII. Summary and Commentary	482
Note 1	483
References	484
Preface to Section III Inhalation Toxicology	497
Chapter 9 Inhalation Toxicology—A Special Entity Radioactive Dusts and Particles	499
Outline	499
Capsule Chronology	503
Overview	507
I. Introduction	508
II. The Manhattan Project Days	510
A. The Earliest Concerns	510
B. Inhalation Work at Berkeley under the Manhattan Project	510

XII Contents

C. Inhalation Work at Chicago under the Manhattan Project	516
D. Inhalation Work at Rochester	533
III. The Postwar Years Begin	550
A. Continuing Work at Former Manhattan Project Laboratories	550
B. Aerosol Science	553
C. The Naval Radiological Defense Laboratory	561
IV. Maturation: The Genesis of Centers for Pulmonary Radiotoxicology	562
A. Hanford/Pacific Northwest Laboratory	562
B. Lovelace Foundation—Inhalation Toxicology Research Institute	588
C. University of Rochester	610
D. Other Laboratories Contributing to Pulmonary Radiotoxicology	627
V. Special Problems	640
A. The Hot Particle Problem	641
B. Tobacco Smoke	651
C. SNAP, ROVER, Kiwi, NERVA	653
D. Organizational Considerations	656
VI. Summary and Commentary	658
References	660
Chapter 10 The Respirable Gases:	677
Outline	677
Capsule Chronology	679
Overview	683
I. Generalities	684
II. The Respirable Gases in the Manhattan District Days	684
A. Noble Gases	684
B. Iodine Vapor	687
C. Other Respirable Gases	688
III. Postwar Work with the Noble Gases and Iodine Vapor	689
A. The Noble Gases, Especially Krypton and Xenon	689
B. Iodine Vapor	697
IV. Tritium and Tritiated Water	706
A. Development of Interest	706
B. Source Terms and Calculations	708
C. Biomedical Research with Tritium at the Whole-Animal Level	710
D. Toxicology of Tritium at the Cellular Level	725
E. The Relative Biological Effectiveness of HT and HTO	726
F. Work with Tritium Abroad	732
V. Radioactive Carbon Dioxide	733
A. Overview	733
B. Sources of Radioactive Carbon Dioxide	733
C. Uptake and Retention	734
D. Effects	736
VI. Summary and Commentary	737
References	738
Preface to Section IV Environment Chapters	745
Chapter 11 Survey of Radioecology:	
Environmental Studies Around Production Sites	749
Outline	749
Capsule Chronology	751
Overview	755
I. Introduction	756
II. The Years of World War II: Hanford and Seattle	757

III. The Early Postwar Years	762
A. Continuation of Hanford Work	762
B. Enter Oak Ridge	768
C. Savannah River Ecology Program	774
D. Other U.S. Activities in the Early Postwar Years	778
E. Work Abroad	784
IV. Radioecology Comes of Age	790
V. The Later Years Around the Production Sites	794
A. Generalizations	794
B. Extensions and Generalizations from the Hanford Work	798
C. Extensions at Oak Ridge	805
D. Work at Other Laboratories in the Later Years	809
VI. Special Topics	816
A. Marine Radioecology	816
B. Effects of Radionuclides on Ecosystems	819
C. More About Nuclear Power Reactors	824
D. The Liquid Metal Fast Breeder Reactor Program	827
E. Transuranics in the Environment	832
F. Tritium in the Environment	835
G. The Environmental Impact Statement	841
VII. Summary and Commentary	843
Note 1	844
Note 2	848
Note 3	850
Note 4	850
Note 5	853
Note 6	857
References	857
 Chapter 12 New Dimension Number Three—Fallout from Nuclear Weapons Tests	 871
Outline	871
Capsule Chronology	873
Overview	879
I. Introduction	880
II. The Story Unfolds	884
A. Trinity (Alamogordo)	884
B. Hiroshima and Nagasaki	887
C. Operation Crossroads—The Dimensions Expand	888
III. The Pacific Proving Grounds	892
A. Overview	892
B. The Resurvey of Bikini	892
C. Sandstone, Greenhouse, and Ivy	895
D. Operation Castle, Shot “Bravo”—The Roof Falls In	897
IV. Trinity Revisited	928
V. The Nevada Test Site	932
A. The Arrangements and Events	932
B. Early Experiences with Fallout at NTS	936
C. The Early Biological Information from NTS	942
D. Offsite Exposures Near NTS	947
E. Onsite Exposures	970
VI. Nationwide and Worldwide Fallout	973
A. Introduction	973
B. The Physical Events and Measurements	974
C. The Biomedical Aspects of Global Fallout	981

XIV Contents

D. Work in Other Countries	1002
VII. Standards for Fallout	1004
A. Early Activities	1005
B. Establishment of Population Exposure Standards	1008
VIII. Dilemmas, Problems, and Progress	1012
A. General Comment	1012
B. Hidden Doses	1015
C. Infant Mortality and Other Correlations	1016
D. Progress	1025
IX. Summary and Commentary	1026
Note 1	1028
Note 2	1031
Note 3	1033
Note 4	1036
Note 5	1038
Note 6	1039
References	1040

**Chapter 13 Biomedical Research Stimulated By the Problems
of Fallout**

Outline	1057
Capsule Chronology	1059
Overview	1063
I. New Laboratories	1064
A. The U.S. Naval Radiological Defense Laboratory	1064
B. The University of Tennessee—AEC Agricultural and Research Programs	1069
C. Cornell University	1074
D. University of California at Davis, Radiobiology Laboratory and Later Laboratory of Energy Related Health Research	1076
E. Southwestern Radiological Health Laboratory	1077
F. Other U.S. Public Health Service Laboratories	1080
II. Special Programs at Established Laboratories	1081
A. Argonne National Laboratory	1081
B. University of California at Berkeley	1083
C. Brookhaven National Laboratory	1084
D. Battelle, Pacific Northwest Laboratories (Hanford)	1085
E. Los Alamos Scientific Laboratory, Now Los Alamos National Laboratory	1088
F. University of California at Los Angeles	1089
G. University of Rochester	1089
H. Lawrence Livermore Laboratory	1089
I. Miscellaneous Other Operations	1090
III. Selected Research Areas	1090
A. Metabolism of Pairs of Elements—The Observed Ratio and Discrimination Factors	1090
B. Aquatic Biology	1118
C. Plants and Plant-Soil Interrelationships	1127
IV. Selected Radionuclides	1147
A. Strontium	1147
B. Iodine	1153
C. Cesium	1156
D. Cerium	1158
E. Other Radionuclides	1160
V. Summary and Commentary	1161

Note 1	1163
Note 2	1165
Note 3	1170
Note 4	1174
References	1175
Chapter 14 Special Environmental Test Projects	1189
Outline	1189
Capsule Chronology	1191
Overview	1193
I. Background	1194
II. Safety Tests for Plutonium at and Around the Nevada Test Site	1195
A. Purpose	1195
B. Project 56, GMX, etc.	1197
C. Test Group 57	1198
D. Operation Roller Coaster	1203
E. Palomares and Thule	1207
III. Long-Term Follow-up—The Nevada Applied Ecology Group	1210
A. Genesis	1210
B. The Problems and Mode of Operation	1211
C. Soil Sampling	1212
D. Plant-Soil Interactions	1213
E. Vegetation	1213
F. Grazing Studies	1214
G. Modeling	1215
H. Comment	1216
IV. Fission Product Field Releases	1216
V. Project Plowshare	1221
A. Development of the Plan	1221
B. Operations	1222
C. A New Interoceanic Canal—The Computational Approach	1222
D. The Cratering Events	1227
E. Gas Stimulation Experiments	1230
F. Alaskan Operations	1232
VI. Related Projects and Events	1233
A. Nuclear Rockets	1234
B. SNAP	1236
C. More Alaskan Operations	1239
D. Mississippi Test	1240
VII. Summary and Commentary	1241
Note 1	1243
Note 2	1244
References	1245
Chapter 15 Movement of Radionuclides Through the Environment	1253
Outline	1253
Capsule Chronology	1255
Overview	1259
I. The Setting	1260
II. The Systems	1262
A. Atmospheric Transport	1262
B. Terrestrial Transport	1267
C. Surface Water Transport	1271
D. Transport in Ground Water	1273
E. Dietary Pathway Usage Factors	1276
F. Commentary	1278

III. Genesis of the Systems	1279
A. General Development	1279
B. Biological Availability	1281
C. Critical Pathways, Critical Nuclides, Critical Populations	1282
D. Recycling	1288
E. Some Landmark Modeling	1289
F. Specifics Regarding a Few Pathways	1291
G. Miscellany Regarding Food and Water	1309
IV. Population and Environmental Dose Assessment, Resuspension, Standards for the Environment	1312
A. Population Dose Assessment	1313
B. Resuspension	1328
C. Environmental and Population Standards	1336
V. Summary and Commentary	1356
Note 1	1359
Note 2	1363
Note 3	1363
Note 4	1364
References	1368

Chapter 16 Internal Emitter Research and Standard Setting: Validation in Man	1385
Outline	1385
Capsule Chronology	1387
Overview	1391
I. Introduction	1392
II. Who's Who	1394
A. The Advisors	1395
B. The Regulators	1408
III. Direct Derivation of Standards for Radionuclides	1412
A. The Radium-226 Standard	1412
B. Standard for Radon-222	1415
C. Possible Interrelation of the Radium and Radon Standards	1417
D. Standards for Natural Uranium	1418
E. Standards for Plutonium	1423
F. Other Radionuclides	1426
G. The Approach of the Federal Radiation Council	1427
IV. The Computational Approach	1428
A. Development	1428
B. The Basic System and Its Research Background	1430
C. Bone Seekers	1432
D. Special Features of the Basic System and Some Modifications	1435
E. Concentrations of Stable Elements	1439
V. Metabolic Data and Metabolic Models	1440
A. Retention Kinetics	1440
B. Metabolic Models	1443
VI. Other Models	1445
A. Lung Model	1445
B. Gastrointestinal-Tract Models	1450
C. Reference Man (Standard Man)	1455
VII. Validation in Humans	1457
A. Plutonium and the Transplutonic Elements	1458
B. Validation of Uranium Limits	1473
C. The Fission Products	1482
D. Other Radionuclides	1484

VIII. Epilogue	1485
IX. Summary and Commentary	1487
Note 1	1490
Note 2	1491

FIGURES

PN-1	A Z-A plot of the transitions in the uranium series	6
PN-2	A portion of the uranium series on an N-Z plot	7
PN-3	The thorium ($4n$) and actinium ($4n + 3$) series on N-Z plots	8
PN-4	The uranium series	9
PN-5	A Z-A plot of the neptunium series	10
1.1	Relation of expired radon/total radium to retention time in man	31
1.2	Influence of the radium content of rats on survival time	35
1.3	Influence of radium content on the survival time of CF1 female and ABC male mice	35
1.4	Illustration of the importance of the dose from mesothorium especially in the early years	48
1.5	Correlation between the classical x-ray score and average cumulative rad (CR) for 326 cases in the MIT-MGH study	51
1.6	Observed tumor cumulative incidence or occurrence in the "Epidemiologically Suitable" cases and low-exposure cases (zero incidence of malignancies) in the MIT-MGH cases measured prior to May 1969	51
1.7	Log-log plot of radium retention after cessation of oral ingestion	54
1.8	Group picture of dial painters at Ottawa, Illinois, plant taken about 1924	55
1.9	Interior view showing dial painters at their desks in the Ottawa, Illinois, plant	56
1.10	Incidence of radium-induced malignant tumors and blood dyscrasias in ANL-ACRH series as of September 1967 (estimated maximum radium burden)	57
1.11	Incidence of radium-induced malignant tumors and blood dyscrasias in ANL-ACRH series as of September 1967 (current or preterminal radium burden)	58
2.1	Early view of the "temporary" buildings housing the MED work at the University of Rochester Medical Center	86
2.2	Later picture of the University of Rochester facility that housed, in part, the Post-World-War-II uranium studies	86
2.3	Group picture of Hematology Group, which worked largely on the MED uranium experiments at the University of Rochester	87
2.4	An outside view of "Site B" of the Metallurgical Laboratory at Chicago	88
2.5	Relative toxicity of twelve uranium dusts on a scale of four to sixteen	92
2.6	Photograph of one bank of the inhalation chambers used for the large postwar inhalation experiment at Rochester	97
3.1	Decay scheme of ^{226}Ra	121
3.2	Composite of dose-effect relationships on the basis of cumulative exposure	159
3.3	Main building and entrance to thermal rock galleries at Boeckstein	162
3.4	General view of Badgastein	162
3.5	Treatments in the thermal gallery, Badgastein	163
3.6	Exposure chamber designed for head-only exposures of ten dogs to radon daughters with uranium ore dust as used at Pacific Northwest Laboratory	170
3.7	Distribution of annual mean radon concentrations in a few New York buildings	177
3.8	Distributions of annual mean working levels in the same New York buildings	178
4.1	Excretion of polonium by the rat following intravenous injection	208
4.2	Percent dose per gram in rats after intravenous administration of polonium chloride	209

4.3	Percent body content per gram in rats after intravenous administration of polonium chloride	210
4.4A	Distribution of retained polonium in the CF1 mouse	212
4.4B	Concentration of polonium in the CF1 mouse	212
4.5	Median lethal times versus dose in Sprague-Dawley rats receiving ^{210}Po intravenously	223
4.6	The mean survival time of Wistar-Rochester rats as a function of polonium dosage	225
4.7	Radioactive "decay" of ^{232}Th plus ^{228}Th showing changes in gross activity with time	237
4.8	Daughter activity build-up from ^{234}Th , ^{231}Th , ^{230}Th , and ^{227}Th present in 1 mc of thorium obtained from Indian monazite	238
4.9	Percent deposition in the skeleton of rats as a function of the quantity of intravenously injected thorium	244
4.10	Thorium-228 dose-response in beagles injected intravenously with monomeric ^{228}Th in citrate solution	258
6.1	The classic bimodal curve for fission-product yield from ^{233}U , ^{235}U , and ^{239}Pu	301
6.2	Early depiction of bone uptake and retention of several fission products as indicated	306
6.3	Illustration of the relatively rapid elimination of several fission products from liver	307
6.4	Early photomicrograph and autoradiograph showing distribution of radioactive strontium in rat femur one week after intraperitoneal injection	309
6.5	Early photomicrograph and autoradiograph of rat femur 21 days after injection of radiozirconium	310
6.6	Comparison of strontium uptake by young normal, young rachitic, and adult rat skeleton	311
6.7	Photograph of the Crocker Laboratory on the University of California Berkeley campus	313
6.8	Concentration of ^{32}P in femur, liver, muscles, gastrointestinal tract, and brain	317
7.1	Periodic table of the elements as it existed at the beginning of the work on the new heavy elements	338
7.2	Periodic table of the elements as it was rewritten by the Seaborg group in the 1940s to show the new actinide series	339
7.3	Effect of valence state on disappearance of plutonium from the blood of rats following intravenous administration	341
7.4	Uptake and retention of actinide-type elements by bone of rats	342
7.5	Uptake and retention of actinide-type elements in liver of rats	343
7.6	Mean accumulated excretion of plutonium in urine and feces of rats after parenteral administration	345
7.7	Cumulative excretion of plutonium, radiostrontium, and yttrium after parenteral administration	345
7.8	Retention of plutonium in various forms in the liver of rats and mice	346
7.9	Photomicrograph and autoradiograph of an adult rat femur seventy days after injection of ^{226}Ra	348
7.10	Photomicrograph and autoradiograph of femur from adult rat injected with plutonium and sacrificed one week later	349
7.11	Similar to figure 7.10 but eight weeks after injection	350
7.12	Excretion of plutonium by patients described in the text	353
7.13	Excretion of plutonium over an approximately five-year period using the data from the patients described in the text	355
7.14	Mean survival time of Wistar-Rochester rats as a function of intravenously injected dose of ^{226}Ra , ^{239}Pu , or ^{210}Po	364

7.15	The same experiments as plotted in figure 7.14 but on a weight basis	364
7.16	Comparative toxicity of ^{226}Ra , ^{239}Pu , and ^{210}Po in the much larger simultaneous intravenous experiment in the Rochester-Wistar rat	365
7.17	Survival curve of Rochester-Wistar rats versus microcuries of plutonium injected per kilogram body weight showing individual points and median points	366
8.1	Relationship between isotope dose and mortality rate in mice	388
8.2	Biological effectiveness relative to radium in increasing net mean mortality rate in mice	389
8.3	Relationship between isotope dose and net rate of mortality with lymphoid tumors in mice	390
8.4	Relationship between isotope dose and net rate of mortality with malignant bone tumors in mice	391
8.5	Life-span shortening with multiple doses of ^{90}Sr	394
8.6	Incidence of osteogenic sarcomas in mice as a function of time and dosage pattern of ^{90}Sr - ^{90}Y	395
8.7A	Retention of several radionuclides in liver	403
8.7B	Retention of several radionuclides in skeleton	404
8.8A	Survival time versus dose for osteosarcoma beagles	419
8.8B	RBE for death with osteosarcomas in beagles showing the effectiveness of ^{239}Pu , ^{228}Th , and ^{226}Ra relative to ^{226}Ra	420
8.9A	Dose-rates in 1-level beagle skeletons	421
8.9B	Cumulative doses in 1-level beagle skeletons	422
8.10	Relative biological effectiveness of alpha-particles from ^{226}Ra and retained daughters, relative to beta-particles from ^{90}Sr and its daughter, ^{90}Y	423
8.11	Experimental design for Hanford experiment with ^{131}I in sheep	436
8.12	Variable growth retardation in three nine-month-old lambs fed $240\text{ }\mu\text{C/day}$ with a control animal of same age	437
8.13	Comparison of Hanford miniature swine with standard porker	438
8.14A	View of the early biology facilities at Los Alamos commonly referred to as the "Rat House" or "Rat Lab"	450
8.14B	View of the "D" Building at Los Alamos in which much of the plutonium metallurgy and chemistry were done	451
8.15	Lead shield for exponential exposure of CF1 mice to Co^{60} γ -radiation	455
8.16	Small animal counter, Los Alamos Scientific Laboratory	456
8.17A	Interspecies correlation between Zn^{65} equilibrium level and body weight	458
8.17B	Interspecific relation of body weights and equilibrium levels for ^{131}I	459
8.17C	Relation between equilibrium factor and body weight for ^{54}Mn	459
8.17D	Interspecies correlation between ^7Be equilibrium levels (estimated from single oral doses to mice, rats, monkeys, and dogs) and body weights	460
8.18	Retention of ^{241}Am in the skeleton, liver, and residual soft tissues of adult <i>Cynomolgus</i> monkeys	474
8.19	Accumulation of ^{241}Am in the skeleton, liver, and kidneys of rats	475
8.20A	Early excretion rates of trivalent actinide elements in the urine of the adult rat: ^{241}Am and $^{249-252}\text{Cf}$	477
8.20B	Early rates of excretion of trivalent actinide elements in the feces of the adult rat	477
9.1	Equipment for "Emanation Experiment" at Berkeley	511
9.2	Schematic diagram of apparatus for in-pile production of short-lived fission products and animal exposure manifold	512
9.3	Percent of total retained activity deposited in the lungs following the intrapulmonary instillation of carrier-free fission products	516
9.4	Diagram of cylindrical "merry-go-round" chamber for the exposure of rats to arc aerosols	520

XXIV *Figures*

9.5A	Right angle jet atomizer, Type II	521
9.5B	Right angle jet atomizer, Type III	521
9.5C	Manifold technique for exposing rats to aerosols	522
9.6	Relative rates of elimination of ^{95}Zr from the lung following inhalation of atomizer ("soluble") aerosol and arc ("insoluble") aerosol	526
9.7	Retention of polonium deposited in lung, upper respiratory passages, and skin of head of rats after exposure to volatilized polonium	535
9.8	Changes in toxicologic responses and body transport of uranium in rats following intratracheal injection of UO_2	541
9.9A	General layout of apparatus for retention experiment	547
9.9B	Diagram of facepiece and valve assembly	548
9.10A	Autoradiographic evidence of plutonium oxide within pulmonary macrophages five days after exposure to a plutonium smoke	551
9.10B	Evidence of aggregated plutonium in lung tissue five days after exposure to a plutonium smoke	551
9.11A	Students at the University of Rochester in early postwar years gaining experience in pulmonary radiotoxicology	552
9.11B	View of control panel, the "Pickle Jar" inhalation chamber and students in industrial hygiene course	552
9.11C	Several "Pickle Jar" inhalation chambers for student use including accessory pumps and aerosol generators	553
9.12	The original hutment for the Hanford "Pharmacology Operation"	563
9.13	Relative distribution of I^{131} in mouse tissues	565
9.14A	Iodine-131 vapor generator	565
9.14B	Mouse exposure chamber within a glove box for exposure to iodine	566
9.15	Whole body turnover of Ru^{106} in mice	566
9.16	Photograph of 100-F Area inhalation toxicology facilities at Hanford	568
9.17A	Long-term dynamic simulation of inhaled $^{239}\text{PuO}_2$	570
9.17B	Long-term tissue burdens of plutonium after inhalation of $^{239}\text{PuO}_2$	570
9.18	Observed biological effects of inhaled plutonium	571
9.19	Relationship between quantity of ^{239}Pu in lung at death and survival time of dogs	571
9.20	Summary—whole-body retention half-times for inhaled plutonium in dogs	573
9.21	Mask assembly for the smoking beagles	580
9.22A	Standard rat exposure chamber	584
9.22B	New design for rat exposure chamber that avoids rebreathing aerosol	584
9.23	Correlation between phagocytic index and log of amount of plutonium present in rat lung	585
9.24	Early Lovelace exposure assembly for small animals	592
9.25	Absorbed beta dose rate to the lungs of beagle dogs from various inhaled radioactive aerosols	597
9.26	Patterns for accumulating 2000 rads total beta dose to the lungs of beagle dogs from various inhaled radioactive aerosols	597
9.27A	Calculated dose relationships for the five planned dog longevity studies	605
9.27B	Schematic representation of the experimental design of longevity studies involving dogs exposed to different monodisperse aerosols	605
9.28A	The Lovelace facilities in September 1983	606
9.28B	The Lovelace Hospital and Clinic in which the inhalation toxicology work began	607
9.28C	The Lovelace project in August 1963	607
9.29A	View of inner corridor of high risk area of Alpha Laboratory at the University of Rochester	614
9.29B	Part of the low risk area of the Alpha Laboratory at the University of Rochester	614
9.30	Floor plan of Alpha Laboratory	615
9.31A	Excretion of polonium after the last of five biweekly intratracheal injections	617

9.31B	Ratios of polonium content of lung to kidney or to spleen	617
9.32	Exposure chamber designed by Rothstein and Hayes	617
9.33	Schematic of retention apparatus developed at Rochester	620
9.34A	Autoradiogram of lymphatic vessel and lymph nodes demonstrating the distribution of plutonium oxide dust particles in the dog— peribronchiolar lymphatics containing plutonium particles	623
9.34B	Autoradiogram of lymphatic vessel and lymph nodes demonstrating the distribution of plutonium oxide dust particles in the dog— lymph nodes illustrating variable content of plutonium	623
9.35A	Degree of radiation changes in lung and lymph nodes graded on scale of 1-5	624
9.35B	Degree of radiation changes in tracheobronchial lymph nodes graded on scale of 1-5	624
9.36	The Anthony J. Lanza Research Laboratories of New York University for research in environmental medicine	633
9.37	Illustration of effect or change in assumed tissue volume on position of dose response curve for incidence of lung cancer	650
10.1	Distribution of inhaled $^{131}\text{I}_2$ in rats	688
10.2	A typical profile distribution of ^{85}Kr in man, based on the coincidence counting mode of the whole-body counter	692
10.3	Lethality curve—guinea pigs exposed to ^{85}Kr via respiratory route	693
10.4A	Thyroid uptake of ^{131}I in rats after inhalation of ^{131}I and ^{127}I	704
10.4B	Relationship of thyroid ^{131}I to $^{127}\text{I}/^{131}\text{I}$ in inhaled air	705
10.4C	Effect of ^{127}I deposition on thyroid ^{131}I and ^{127}I in rat and dog	705
10.5	Projected tissue dose rate from tritium in man	709
10.6	Tritium activity (as HTO) in urine of rats during inhalation of an atmosphere containing HT or HTO	714
10.7A	The observed concentrations of tritium in urine and the least-squares fit of the data	715
10.7B	The percentage of assimilated tritium as calculated by an absorbing Markov chain	715
10.8A	Interspecies correlation between log daily water loss and log body weight	717
10.8B	Interspecies correlation between log body water content and log body solids content	717
10.9	Brookhaven Tritium Toxicity Program	724
10.10A	Splenic weight loss in mice at 5 days as a function of dose of tritium beta-particles and radium gamma-rays	728
10.10B	Thymic weight loss in mice at 5 days as a function of dose of tritium beta-particles and radium gamma-rays	729
10.10C	Uptake of Fe^{59} by rat red blood cells as a function of dose of tritium beta-particles and radium gamma-rays	729
10.11	The ranges of uncertainty in RBE for tritium	730
10.12	Oocyte responses to ^3HOH and ^{60}Co gamma-rays given in short (5-day) and protracted (33-day) exposures compared	730
11.1	The Fisheries Laboratory (Building 146-F) at the Hanford plant during the MED days	758
11.2	Geographical distribution of "radiation density" in snails sampled during September 1952	764
11.3	Biology boat used for sampling in Columbia River in early days	766
11.4	Inoculating trees with radioisotopes—Oak Ridge Ecological Research	771
11.5	Environmental monitoring locations around the Savannah River Plant on the South Carolina side of the Savannah River	775
11.6A	Radionuclide releases and calculated doses from operations of Savannah River Plant	776
11.6B	Radiation dose originating from Savannah River Plant for nearby resident compared to doses from other sources	776

11.7	Average concentration factors for ^{90}Sr in Perch Lake food web	785
11.8	Decay curve of I^{131} in milk near the Windscale Works of the United Kingdom	788
11.9A	Facilities for ecological research at Pacific Northwest Laboratory (Hanford) as they existed in 1964	799
11.9B	Battelle, Pacific Northwest Laboratories' marine research facility at Sequim, Washington, on Puget Sound	800
11.10A	Oak Ridge Ecology Program, summer 1955	805
11.10B	Oak Ridge Ecological Sciences Division, summer 1978	806
11.11	Geographical distribution of radiological survey sites	808
11.12	Cesium-137 content of sediment water and biota in the Hudson River: averages of 1962-72 along with fallout and reactor inputs	813
11.13	United States Department of Energy, Office of Health and Environmental Research, transuranium elements research program	829
11.14A	Values of the maximum dose rates from four principal radionuclides to the most exposed individuals from local, regional and global sources	842
11.14B	The collective dose-equivalent commitments, in Sv, for four radionuclides that can be avoided by complete retention and isolation for 10^4 a of radionuclides that would otherwise be emitted	842
12.1	Eastman Kodak film affected by the fallout from the Trinity Shot, Alamogordo, New Mexico, 1945	886
12.2A	Northern Marshall Islands	889
12.2B	Operation Crossroads: The approximate position of the target area of the 1946 test detonations	889
12.3	Enewetak Atoll	893
12.4A	General pattern of fallout from March 1, 1954, test at Bikini	899
12.4B	More on radiation doses on individual atolls at the same time	900
12.5	Beta radiation lesions of the feet four weeks after exposure and sequence of healing	902
12.6A	Steel room used for whole-body gamma spectroscopy on the Marshall Islands	903
12.6B	Arrangement of lead bricks used for whole-body counting	904
12.7A	The <i>Fukuryu Maru</i> No. 5 during her period of quarantine	912
12.7B,C	Radiation survey of tuna conducted by Tokyo Metropolitan health authorities at the Tokyo Central Fish Market, 1954	913
12.7D	Sign at fish market in Japan, March 1954	913
12.8A	Dr. Kenjiro Kimura, noted radiochemist, at conference discussing Japanese findings	915
12.8B	Early meeting of American representatives with Japanese concerning the exposed fishermen	915
12.9	One of several meetings of American scientists called by the Joint Committee on Atomic Energy of the U.S. Congress to discuss the biomedical significance of fallout	916
12.10	Average gross beta activity of marine organisms from Guam, Palau, and the Gulf of Siam, 1958-1959	918
12.11	Distribution of fallout radioisotopes at Rongelap Atoll, 1959	924
12.12A	A latex-covered plastic film to collect falling dust	938
12.12B	Dr. Eisenbud with an array of pans for catching fallout	938
12.13	Typical trajectories of fallout from Nevada Test Site detonations	948
12.14A	Adjusted leukemia mortality rates per 100,000 population according to year of occurrence for counties with high and low fallout	958
12.14B	Adjusted leukemia mortality rates per 100,000 population for high-exposure and low-exposure cohorts for counties with high and low fallout	959
12.15A	Chicago fallout in 1955	979
12.15B	Pittsburgh fallout in 1955-1956	979

12.15C	Worldwide Sr^{90} fallout rates in 1954	979
12.16	Strontium-90 in air, Washington, D.C.	980
12.17	Air sampler and portable generator	980
12.18	Millicuries of Sr^{90} per-square mile in soil, 1955	981
12.19A	Variation of ^{90}Sr in various diet components in New York City, 1959-1975	984
12.19B	Variation of the ^{90}Sr in various diet components in Denmark, 1960-1974	984
12.20	Variation of ^{90}Sr in bone in Australia and in New York City, 1955-1975	985
12.21	Correlation of Cs^{137} levels in the U.S. population with levels in milk	986
12.22	Whole-body concentration of ^{137}Cs in normal New Mexico population	988
12.23	Average concentration of radionuclides in milk samples from Public Health Service pasteurized milk network	997
12.24	Strontium-90 concentrations in pasteurized milk	997
12.25	View of part of the procedure for analyzing milk for fission product radionuclides	998
12.26	Part of the procedure for separating out noble gases from fallout fission products	999
12.27	Fetal death rate for Missouri showing the "excess" over the expected rate based on the 1935-1950 regression line	1017
12.28	Fetal death rate reported per-1000 live births versus time for New York State and California before and after the onset of nuclear weapons tests in 1951	1018
12.29	Strontium-90 deposition before 1954, based on gummed film measurements	1020
13.1	Alamogordo Cow Number 52, the last surviving member of the herd accidentally exposed to fallout from the Trinity shot in July 1945, and calf	1071
13.2	Arrangement for separate collection of urine and feces from the dairy cow ..	1072
13.3A	Southwestern Radiological Health Laboratory, Las Vegas, Nevada	1077
13.3B	Moderately close-up view of the Southwestern Radiological Health Laboratory on the Nevada Test Site	1078
13.3C	Further out view of the Southwestern Radiological Health Laboratory Farm on the Nevada Test Site	1078
13.3D	The Public Health Service version of a bovine metabolism cage as installed at the large-animal farm at the Nevada Test Site	1078
13.4	"Big Sam," one of several rumen-fistulated steers in the beef herd kept at the Southwestern Radiological Health Laboratory	1079
13.5	Plan of the Hanford experiment on ^{90}Sr in miniature swine	1086
13.6	Laboratory facility at Hanford for housing miniature swine showing individual feeding compartments and ^{90}Sr pellets being fed	1086
13.7	Observed Ratio (bone-diet) during period of chronic feeding of diets of various total calcium content to rats	1096
13.8A	Observed Ratio (bone-diet) in rats fed from weaning on ^{90}Sr - and ^{45}Ca -labeled diets of various total calcium contents	1096
13.8B	The same data plotted with shading for the ranges	1097
13.9	Effect of dietary calcium on skeletal deposition of Sr^{90} in rats	1097
13.10	$\text{OR}_{\text{body/diet}}$ as related to age of young children	1098
13.11	Observed Ratio as a function of age in beagles	1098
13.12	Distribution of Sr^{90} in the soil profile and ratio of Sr^{90} to calcium in ryegrass	1100
13.13	Plant discrimination toward ^{90}Sr at varied calcium levels	1101
13.14	Ecological discrimination against Cs^{137} with respect to potassium	1103
13.15	Expression of discrimination in terms of rate constants	1108
13.16	The discrimination against the re-absorption of ^{85}Sr by the renal tubules	1110
13.17A	Depletion curves for relative activities of ^{131}I from sea water by bivalves	1122
13.17B	Depletion curves for relative activities of ^{85}Sr from sea water by bivalves	1122

XXVIII *Figures*

13.18	Uptake and distribution of plutonium, americium, curium, and neptunium	1138
13.19	Transverse section of glove box and aerosol exposure wind tunnel	1143
13.20A	Relationship between nuclear volume and daily dose rate required to produce severe growth inhibition in twenty-three species of plants chronically irradiated	1146
13.20B	Relationship between radiosensitivity and degree of polyploidy in 175 species chronically irradiated plants	1146
13.21A	Dose-response relationship for the effect of ^{144}Ce on the lung and other organs of beagles after inhalation of labeled fused aluminosilicate particles	1159
13.21B	Dose-response relationship for the effect of ^{144}Ce on the lung and other organs of beagles after inhalation of ^{144}Ce labeled chloride aerosols	1160
14.1	Map of Nevada Test Site, Tonopah Test Range, and the surrounding buffer region of the Nellis Air Force Range, in South Central Nevada	1197

FOREWORD

The invention of the cyclotron, the construction of nuclear reactors, and the explosion of nuclear weapons unleashed upon the world vast quantities of new substances, radioactive isotopes, that created unprecedented opportunities and problems for mankind, far beyond those posed by the radioactive isotopes that occur naturally in the earth. The availability of cyclotron-produced radioisotopes in the 1930s was quickly seized upon by medical scientists who saw opportunities for their use in diagnosis and therapy and by biological and chemical scientists to put radioactive labels on chemical compounds to trace them through chemical and biological processes. However, except for the saga of the radium dial painters and patients, the serious efforts began in the 1940s with the discovery of fission and the construction of nuclear reactors, which led to large quantities of many radioisotopes becoming available. This also stimulated concern about the potential health risks associated with the production and use of radioactive isotopes and led to the development of a large health and environmental research program by the Manhattan Engineer District (MED) and Atomic Energy Commission (AEC), which also undertook research on the medical applications of radioisotopes.

Thus began an important and productive period in biological and medical research in the United States, which led the world in understanding the behavior of radioactive isotopes in living organisms and the environment. How these research programs developed, who developed them, and the progression of scientific knowledge about radioisotopes in biological material and the environment should not be lost from the record of major accomplishments of the MED, the AEC, and its successor agencies, the Energy Research and Development Administration, and the Department of Energy. Dr. J. Newell Stannard's *Radioactivity and Health: A History* assures that will not happen. It is a fascinating story of scientific research and of people who provided leadership and made important discoveries. It is the story of how science successfully dealt with the potential hazards of working with highly radioactive material; undertook research to understand its behavior and effects in biological and environmental media; applied this knowledge to the technology for handling radioisotopes safely and to the establishment of radiation protection standards, which have guided the design of laboratories, hospitals, and factories where radioisotopes are produced and used.

Newell Stannard, being part of this important scientific endeavor and acquainted with all of the principal scientists and administrators involved, has accomplished a monumental task in writing this volume, capturing in it the essence of these scientific achievements. This volume is much more than a history of a particular segment of science, documenting who did what and when;

it also deals with the development of scientific concepts, the progression of discoveries, the events that paralleled and influenced the scientific program, and the application of the knowledge to protection of human beings and the environment. Newell is eminently qualified to have written this history because he was a pioneer in research on health effects of radioisotopes, and he has continued to contribute to the field in numerous ways for fifty years. A brief summary of his career will help the reader recognize his qualifications and understand his incentive for writing this history.

During World War II, Newell spent several years doing research on respiratory physiology, as a naval officer at the Bureau of Medicine and Surgery in Washington, D.C., and also as a member of the staff at the National Institute of Health. After the war, he was invited to the University of Rochester School of Medicine to establish a graduate education program in the field of atomic energy as applied to health sciences. Beginning as assistant professor of radiation biology and chief of the radiation toxicology section in the Atomic Energy Project, he became its assistant director for education in 1948, when the first AEC fellowship students arrived at the University to begin a year of graduate study in radiological physics (later to be called health physics). Under Newell's leadership, this master's degree program was soon expanded to include Ph.D. programs in radiation biology, biophysics, and toxicology. These were the world's first Ph.D. programs that applied atomic energy to the life sciences and medicine. The AEC Fellows were soon joined by graduate students from all of the U.S. armed forces, including medical officers, for advanced courses in nuclear science, and by students from throughout the world sponsored by the International Atomic Energy Agency.

Newell began his own radiobiological research in two areas: effects of radiation on cell membranes and the biological effects of alpha-emitting radionuclides. The first represented an early attempt to understand the mechanism of the interaction of ionizing radiation on living cells. The second was directed primarily at developing information about the behavior and biological effects of polonium. Polonium, an alpha-particle emitter, was an early component of nuclear weapons and was being handled in relatively large quantities at MED and AEC laboratories and production plants. The research accomplished by Newell and his colleagues is the definitive work on the biological aspects of polonium and was a significant biomedical contribution to the atomic weapons program.

Newell and a colleague carried out one of the first repeated-insult studies by administering regular/periodic doses of polonium to rats by intravenous injection, to study the pathological findings of radiation under a relatively constant body burden. By comparing the findings in rats with a maintained body burden to those observed following a single injection, they were able to make comparisons that had widespread practical implications.

Newell's work with polonium and his earlier work in respiratory physiology led to his being given responsibility at the University of Rochester, in about 1952, for research on the inhalation of radioactive aerosols. Although the Atomic Energy Project at the University already had more than five years' experience exposing animals to aerosols of uranium compounds, this new program was the first to involve highly radioactive alpha-emitting materials such as polonium and plutonium. Newell is therefore truly the founding father of research on inhaled radionuclides. He and his associates developed completely new methodologies for containing radioactive aerosols for exposing rodents and dogs by inhalation,

while avoiding contamination of personnel and of facilities in which the work was performed. This was the beginning of a program that trained many graduate students who contributed not only to research on inhaled radionuclides at Rochester but carried the techniques to programs at other laboratories. Newell's pioneering work at the University of Rochester became a basis for the AEC's large programs on inhaled radionuclides at other institutions.

Newell was a program director in Test Group 57 of Operation Plumbbob and, as such, had responsibility for organizing and carrying out various biological experiments at the Nevada Test Site. These field studies were aimed at assessing the risks associated with nonnuclear accidents involving nuclear weapons. Results from this work serve as a basis for certain present safety criteria in the weapons program, and they represent a one-time collection of crucial data from a type of study that will never again be repeated. He was able to add some quality assurance philosophy to studies carried out under field conditions and, thus, added greatly to the credibility of biologically oriented field trials.

In addition to this work in radiation toxicology, Newell recognized early the importance of understanding the physical-chemical behavior of solutions and suspensions of radionuclides. Only with the atomic age was one able to measure the chemistry of extremely low concentrations under a wide range of pH. Under Newell's supervision, knowledge of the behavior of radiocolloidal suspensions greatly expanded. The relationship of radiocolloidal suspensions formed under various chemical conditions to their metabolic behavior in experimental animals added significantly to our quantitation of the role of the reticuloendothelial system as a function of the physical-chemical state of a substance entering the circulatory system. Such work emphasized Newell's versatility in scientific fields that at times diverged greatly from his basic education and training.

Newell's educational and research activities have been vital to many programs related to atomic energy, including nuclear medicine, nuclear power, weapons, and space. Hundreds of graduates from the programs developed under his supervision can today be found in positions of responsibility in research and in radiation protection—in government agencies such as the Department of Energy, Nuclear Regulatory Commission, Environmental Protection Agency, National Institutes of Health; in the armed forces; in nearly all U.S. nuclear power plants; in national laboratories; in universities; and in hospitals.

Throughout his career, Newell has served with distinction on numerous national and international committees concerned with radiation protection. His publications, numbering well over one hundred, represent significant contributions to the study of radioactivity and health.

Newell is a rarity among men and among scientists. His dedication to the monumental task this book represents attests to that, especially because he undertook the project after retiring from his dynamic and productive teaching and research career. Newell's professional achievements are matched by his extraordinary personal virtues. He is thoughtful, compassionate, trusting, and friendly; he always sees the best in everyone.

It is frequently lamented that major scientific endeavors are not documented while the principals are living. This book addresses that problem directly. In preparing it, Newell interviewed nearly all those who made the scientific contributions discussed and those who made the decisions that implemented the research. In some instances, when people were interviewed long after the events, Newell noted the differences in their individual memories. He has skillfully dealt with these discrepancies so that history is served without personal bias.

In addition to the personal interviews, Newell conducted a massive literature search, visiting libraries throughout the country. His references include citations of obscure publications and previously classified material, as well as the vast open literature produced over the past century. His task has been long and arduous, but one he has undertaken with enthusiasm and consummate skill. He has not been alone in his endeavor. Dr. Raymond Baalman, of Battelle, worked closely with Newell throughout. Ray, like Newell, is a rarity for a scientific research institution. After earning a doctorate in French literature and teaching several years, Ray was invited to join the Environment, Health and Safety Research Program at Pacific Northwest Laboratory as scientific editor and writer. He demonstrated exceptional skills in working with scientists to prepare technical papers and reports. One of his early major assignments was to assist the author of this Foreword in the preparation of a report for the International Commission on Radiological Protection, which appeared as ICRP Publication 31, *The Biological Effects of Inhaled Radionuclides*. With this background, he was well prepared to work with Newell throughout the production of this comprehensive history of the research conducted on the health and environmental aspects of radionuclides.

This book is a valuable contribution to the history of science because it records in a cogent and clear manner this extraordinary period of scientific accomplishments. It will help government administrators understand the past as they plan future research programs; will tell young scientists entering the field what has come before and who has made significant contributions; will remind those scientists who participated in the research of the magnitude of this important segment of American science; and will help those responsible for establishing and recommending radiation protection standards know what information is available. Finally, it will reassure those working with radionuclides and members of the public that the protection of their health and that of their descendants, as well as the protection of the environment in which they live, has been addressed in a major scientific endeavor for more than a half century.

William J. Bair
Manager, Life Sciences Center
Battelle, Pacific Northwest Laboratories

PREFACE

I. Purpose and Scope

This book concerns a facet of biomedical science that has had less systematic review than many other aspects, with a few notable exceptions. It concerns the history of our understanding of the behavior of radioactive materials (radioisotopes, radionuclides) in living organisms and in the environment and the gradual acquisition of knowledge regarding their effects. There can be no doubt that many thousands of lives have been saved, prolonged, or made more tolerable by the myriad uses of radioactive materials in clinical medicine. This began with the use of radium as a source of gamma rays and continues through today in the use of very large radioisotope sources and in the very active field of nuclear medicine. In addition, many thousands more of us have been affected positively by the biomedical discoveries made possible by the uses of radioisotopes as tracers in the study of biological processes. In the aggregate, these beneficial effects outweigh, by far, even the horrendous casualties of the atomic bombings of Japan. However, they do not attract as much attention, because they occur one by one.

Research on the biological effects of ionizing radiation began long before atomic bombs, weapons testing, fallout, or other modern concerns. It began quite soon after the discovery of x rays by Roentgen. Historical accounts have been many and ample, but, in general, they emphasize the biological effects of ionizing radiation from sources external to the body, such as x rays, gamma rays, neutrons, etc. Comprehensive historical reviews of the work with radioactive materials have not been so numerous or so ample, even though the history begins as early as the fifteenth century. Work with radioisotopes has always been inherently more complex than that with external sources, because the radionuclides behave chemically like their nonradioactive congeners and have, in addition, the complexities of differences in chemical form. Thus, their dosimetry is difficult indeed. As a result, investigators interested in basic mechanisms quite naturally chose sources with fewer complexities and sources that could be turned off at the flick of a switch rather than lingering (and delivering dose) for varying lengths of time. Nevertheless, the accumulated information with radionuclides is now substantial, even unwieldy in volume, and a formal history is clearly in order.

There are other reasons for this effort. The book concerns facets of a period of American scientific and technological history that can never be repeated, viz., the release of the energy of the atom. There are those who bemoan man's discovery of the energy in the atomic nucleus and ways to release it and state that the world would be much better off had the discovery not been made.

Such reasoning is specious. Renowned physicists have stated many times that once radioactivity had been discovered it was only a matter of time before the obviously high energies were made subject to release. When Lise Meitner described uranium fission and its energy release just before the storm of World War II broke, it became clear that the only cogent question was who would get there first. Would those who bemoan our efforts toward the release of atomic energy feel the world would now be a better place if Hitler had gotten there first? We had no choice.

In this context, a distinguished cadre of biologists and physicians devoted all of their energies for many years, during and after World War II, to protecting the workers, communities, and the environment generally from the possible deleterious effects of the enormous quantities of radioactivity expected to be produced, if the process worked; also, to learning as much as possible about the behavior of the numerous old and new substances in the body and their effects. Fortunately, they could build upon the experience already gained with radium, e.g., the dial painters, radium chemists, and patients who received radium as a therapeutic nostrum; early experiences with other naturally occurring radionuclides; and the growing amount of information concerning the uranium miners, particularly in Europe. This book describes these early beginnings, as well as the World-War-II and post-World-War-II investigations that were its initial *raison d'être*.^(a)

It should be clear that the hundreds of biomedical scientists involved in those efforts mounted complex long-term experiments whose results were slow to come, maddeningly slow, compared to parallel efforts in fields like molecular biology. Some of the work is still in progress, and more needs to be done. Nevertheless, at every turn, these investigators' eyes were peeled for any indications of revelation of a new phenomenon of nature or modifications of older phenomena. Contributions to "basic" mechanistic research were significant though less obvious than a similar effort in a field less oriented to practical matters.^(b)

Even though there is much yet to learn, the intensity of work in this field (except for that in nuclear medicine) is much lower now than in the days of peak activity. There are many reasons. The largest mysteries have been uncovered, even solved to some degree. The problems of chemical toxicology are now requiring efforts not dissimilar to those in the most active days of radionuclide research. Competition for funds is fierce, thanks to the federal deficit and a general disinclination to spend at the old rate on nuclear matters, no matter how far they may be from bombs or reactors. A few of the researchers most involved have become discouraged and disillusioned. As they approach the closing days of their careers, they wonder if their efforts made any difference or were appreciated. It is hoped that the substance of this book can help such individuals to renewed enthusiasm for their contributions and those of their colleagues. Those coming upon the story for the first time or for a first

(a) The initial idea for the book was to unearth and describe facets of the World War II effort that had never been published. However, the author's New England conscience would not allow so circumscribed an effort. Instead, he decided to go back to the earliest experiences and follow through on all possible fronts, except actual clinical medicine. The result is a more unwieldy but, he hopes, a more useful volume.

(b) It is hoped that many of the leads coming from these works can now be followed out in more frankly mechanistic experiments (see chapter 21).

broad look should develop a sense of pride in the accomplishments and gratitude to the people who contributed so generously of life and substance for relatively modest material rewards.

II. The Modus Operandi

This book is designed to be primarily a history of research facts, measurements, and ideas and the people who developed them. "Research" is defined very broadly to include from bench-top laboratory experiments to worldwide environmental investigations. The book is not a monograph or a critical review. The findings and conclusions are presented largely as the investigators saw and reported them. Frequently, the discussion utilizes the terminology and units of the time, unless they are truly antiquated or potentially unclear. It is only when the work being reported is markedly iconoclastic or obviously wrong that I chose to make special note of it or to correct it. Nevertheless, except for direct quotations, the language is mine, and I take full responsibility for it.

The working materials for this volume included published papers in scientific journals, books, published conferences and symposia, personal interviews with over 100 individuals, some of them more than once (see Appendix A), and, particularly for the 1940-1950 decade and for the large government-supported laboratories to the present day, "in-house" reports. These reports frequently represent the only comprehensive archive of what was done and why. Unfortunately, this source is drying up because of storage problems and must be retrieved by ever more complex and inconvenient means. For this reason, special efforts have been taken to review and document these sources, though even now some sections of the field are partially inaccessible.^(a) Nevertheless, the volume of all materials available for this review was surprisingly large and the quality much better than might have been expected for so complex and disparate a field approached under conditions of considerable urgency. It did require diligent searching, however!

For convenience, the book is divided into the following major sections:

- I. Naturally Occurring Radioactive Elements (chapters 1-4)
- II. The Manmade Radioisotopes (chapters 5-8)
- III. Inhalation Toxicology (chapters 9 and 10)
- IV. Environment Chapters (chapters 11-15)
- V. Instrumentation (chapters 17 and 18)
 - chapter 17 written by Howard L. Andrews
 - chapter 18 written by Ronald L. Kathren
- VI. Therapy and Nuclear Medicine (chapters 19 and 20)
- VII. Concluding Comments (chapter 21)

The reader is invited to explore further the planned contents of each major section by perusal of its individual preface and the several chapter headings and outlines.

The basic pattern is chronological, but in moderately large chunks. Slavish devotion to a year-by-year rendition of the events was considered both

(a) Poor housekeeping and/or lack of foresight have made their contributions to this inaccessibility. Only in rare instances did a continued high-security classification exclude a document from citation in this chronicle.

unnecessary and likely to be boring. The time quanta are, instead, chosen to fit the progression of events in the subject under discussion. However, to aid the reader interested in specific years and a moderately fine-tuned chronology, all chapters, except the summary one (chapter 21), contain a "Capsule Chronology," which selects out pertinent events by year.

Historical treatises in science can be relieved somewhat of the ever-present urge to be current or present the latest information. In the initial stages, it was decided to cut off detailed accounts at about 1980. As the project grew, it became necessary to discuss events of more recent years, especially if important new developments occurred that bore on the subject at hand. Many of these are handled by "Notes Added in Proof." A short discussion of the bearing of the researches described herein on the Chernobyl reactor incident has been added to the final chapter. Nevertheless, the reader should not assume that routine developments since about 1980 will be included. The recent literature is readily available for these.

Since our focus is largely on programs and the people and places involved, many of the chapters present developments institution by institution. In other cases, e.g., the uranium-miner saga, the contributions of single institutions merged to such an extent that the progression of ideas and findings seemed more pertinent than the individual institutions. Even so, the contributions of people and places are kept distinct. There is little anonymity anywhere in the book.

For the reader's convenience, each chapter (with a few exceptions) has also an Overview, which tells what it is proposed to cover; an Outline; and a Summary and Commentary, which allow some generalizations on what was said in the chapter. Each of these was considered important for so long a work. Nevertheless, they make no pretense at complete coverage. These, along with the "Capsule Chronologies," should provide a useful synopsis of the material in the text.^(a)

It has been necessary to concentrate on work done in the United States, especially for certain periods. This is especially true for the years of World War II. In much of the research, there was no one else working on it at this time! For the pre-World-War-II years, by contrast, the discussion could be much more international. Indeed it could be nothing else. For the post-World-War-II years, the sheer volume of new research made selection necessary. The author's research experience and the sponsorship (but not control) of the work indirectly by the U.S. Department of Energy (see Acknowledgments) also led to emphasis on work in or concerning U.S. laboratories. In some areas, much worthy work done in other countries had to be given short shrift, and this is regretted.^(b) In other areas (e.g., chapter 19 on therapeutic removal of deposited radionuclides), U.S. contributions and those of other countries were so inextricably bound together that the chapter is a presentation of efforts throughout the world.

Obviously, precision and sensitivity of measurements changed markedly over the years of this review. There is now greater precision and less variability. The chapters on instrumentation reflect briefly on this fact. However, since the

(a) The author's worries about the considerable length of this history were assuaged by the sponsor's encouragement to do a "complete job," for it would "never be done again."

(b) Perhaps there will be an opportunity to make up this deficiency in another work.

1920s, except for de novo developments such as accelerators, nuclear reactors, whole-body counters, etc., the improvements have done more to change convenience and reliability than the fundamental ideas about biological phenomena that could be deduced from the measurements. We take several occasions to salute the skill of the early investigators for finding as much as they did with primitive and temperamental methodology. Instances where improved methodology brought a quantum jump in ideas are singled out. Otherwise, the gradual improvement in measurement abilities and in sophistication of ideas is considered an inherent part of the developments chronicled, and readers are expected to take their cue from the date of the work under discussion.

In any work of this length done primarily by a single author, and despite the diligent efforts of an excellent editor and many reviewers, some errors are bound to have slipped by. They may have been sins of omission as well as commission. For these, the author takes full responsibility. Also, much worthy research had to be consciously omitted. The author takes full responsibility for such omissions, also. (Something had to be done to save space!) If there are serious errors or omissions, the author would appreciate knowing and will do what he can to make adjustments.

A word about the ordering of the reference lists might be helpful. References are grouped at the end of each chapter in the following way: multiple citations of a single author, in chronological order; two or three authors, in alphabetical order and then chronologically, if necessary; four or more authors are treated as "et al." in the text and are grouped alphabetically and then chronologically in the reference list. Tables and figures taken from other works have been reset and redrawn, preserving, in most instances, the original captions, units, footnote styles, and so forth. Modifications have been noted. My notes to tables are set below the full rule at the end of the table.

Finally, let it be mentioned in closing this section:

The losses of history are indeed irretrievable; when productions of fancy or science have been swept away, new poets may invent and new philosophers may reason; but if the inscription of a single fact be obliterated, it can never be restored by the united effort of genius or industry. (Edward Gibbon, *Miscellaneous Works*, III. 561.)

Surely not all "facts" are so immortal, nor can we ever hope to keep them all. Science is a continuum. Nevertheless, the present volume tries to preserve as much as reasonably achievable from a special facet of a special era. Readers are privileged to skip facts when they become too numerous, but it is hoped they will follow the trains of thought.

III. Acknowledgments

One of the grand emoluments of teaching is to see the extension and maturation in students of what the teacher could play a part in initiating. The author has been privileged to have a part in launching the careers of many excellent scientists who have gone on to productive and important places in our particular sphere. For this book, the author is profoundly grateful to his first Ph.D. student at the University of Rochester, Dr. William J. Bair, now Manager of the Life Sciences Center at Battelle, Pacific Northwest Laboratories. Dr. Bair, along with Dr. Bruce Wachholz, another Rochester graduate, first suggested the idea. Dr. Bair stimulated and managed a contract between the Department of Energy and Battelle on which the author became a consultant. He graciously accepted, indeed encouraged, a considerable expansion of the scope of the project and

has been patient as the time extended well beyond what was originally anticipated. Furthermore, he has read every chapter and contributed important suggestions from his broad experience. Finally, Dr. Bair provided needed technical assistance from his organization in the preparation of figures, word processing, typesetting, and many other operations not available to someone, like myself, in retired status.

Second, the author wishes to express his gratitude to Dr. Ray W. Baalman, senior editor/writer in the Life Sciences Center at Battelle, Pacific Northwest Laboratories, and admiration for his skillful and productive editorial work. Indeed, this book has, at certain periods, I am sure, consumed almost all of Dr. Baalman's time and become almost as much a part of his life as it has of mine. It takes special talent to be an editor who can impose high standards, yet avoid nitpicking or unduly pressing his own ideas of writing style. I hope Dr. Baalman has learned as much about science from this effort as I have learned about language from him. Dr. Baalman used *A Manual of Style* from the Chicago Press as his guide.

The book was typeset at Battelle, preliminarily by Mrs. Mary Jochen and Mrs. Sue Vickerman. This monumental task was taken over by Mrs. Sandie Blakley, a typesetter par excellence, who could spot a column of figures that did not add up correctly, as well as inconsistencies in mathematical notation. She also did the lay-up of the final manuscript, with assistance from Mrs. Sara Nelson and Mrs. Rose Watt, who, in addition, typeset the indexes from copy typed by Mrs. Marianna Cross. The cover was designed by Ms. Dorothy Siebe of Boeing Computer Services, Richland.

Dr. Baalman received editorial assistance on the references from Ms. Kelly Parnell and Ms. Terri Gilbride, and on the indexes from Ms. Dev Felton, all of Battelle. Mrs. Jan Tarantino helped to ensure the quality of the book's appearance, assisting the editorial staff with her keen eye for detail.

The author is not an instrument man, even though he appreciates the importance of using the best available, kept in the best of condition. He was very fortunate to persuade Dr. Howard Andrews, PHS retired and emeritus from the University of Rochester, now living in Jamestown, Rhode Island, to prepare a chapter on the major developments in laboratory instrumentation for detection and measurement of radioactivity and Ronald Kathren, of Battelle and the Hanford Environmental Health Foundation for a chapter on the history and development of instrumentation for field use and for monitoring. Both have had long experience in the area. In addition, Kathren is an aficionado in the history of the science of radiation and has a collection of old instruments.

In Appendix A, the numerous interviews carried out by the author are listed by name, place, and date. Thanks go to all who gave generously of their time and talents for a quasi-oral history used to start the project. Many of these individuals and others read chapters or portions of chapters for accuracy and coincidence with their personal experiences. Among these are Edward Alpen, Howard Andrews, William J. Bair, Robert Bennett, Leo Bustad, Austin Brues, Melvin Carter, Arland Carsten, George Casarett, Walter Claus, Jared Davis, Joe Deal, Geneva Douglas, Merrill Eisenbud, Asher and Miriam Finkel, Marvin Goldman, James Haggerty, John Healy, Harold Hodge, Ronald Kathren, Harry Kornberg, Sidney Marks, Charles Mays, William Myers, Thomas Noonan, Claire Palmiter, Orr Reynolds, James Robertson, Paul Rohwer, "Van" Romney, Glenn Seaborg, Allyn Seymour, Charles Shilling, Betsy Stover, Robert Thomas, Burt Vaughan, Robert Watters, Ivan White, and Robert Wilson. Some of these supplied

illustrations or other materials as indicated in the captions or text. The ideas and alterations suggested by each of these have been responded to insofar as possible, but this author still assumes responsibility for the final product despite the impressive cadre of people who volunteered to give from a few comments to in-depth reviews and the submission of additional material. As mentioned elsewhere, the author also made considerable use of the historical perspective and files of both Dr. Patricia Durbin and Ronald Kathren.

The manuscript was reviewed in both the Washington, D.C. headquarters of the Department of Energy and at the Richland Operations Office of DOE. Many helpful suggestions were received but no sign whatsoever of an intent to influence content.

The Department of Community and Family Medicine^(a) of the University of California, San Diego, made possible, by a courtesy appointment, entree to the enormous resources of the University of California library system, a campus office and a place to work for the author and for student assistants who helped with the necessary research and kept the author's reprint collection viable. Special thanks go to Mary Catherine Box-Carlsson, who exhibited remarkable abilities to ferret out unusual journals and documents in the formative stages of the work. Benelia Santos helped in the final phases of the project at U.C.S.D.

The primary chore of typing the manuscript and getting it ready for its trip to the word processor was handled competently and, with a serenity that meant much to the author, by Mrs. Barbara Pattinson who worked through R.B. Bookkeeping and later Donald McLean and Co. in Rancho Bernardo. Every word of the manuscript was typed, sometimes many times, by Barbara, who, as a result, knows much more science than she gives herself credit for. Her faithful and effective service over a period of over five years is acknowledged with special thanks.

In addition to the major contributions by Drs. Bair and Baalman at Battelle, described earlier, many individuals in the organization did yeoman duty in preparation for publication. The author is grateful to each of these who participated at one time or another. Special thanks go to Mrs. Grace Miller who handled the chore of obtaining copyright releases.

Finally, but far from least, the author thanks his wife, Grace, for patience and encouragement through the years when BOOK dominated most of the author's working and some of his sleeping hours.

(a) Chaired by Dr. Elizabeth Barrett-Connor.

Preface to Chapters on Naturally Occurring Radioactive Elements

We begin this book by considering research on the biomedical aspects of the naturally occurring radioelements. These provided man's introduction to the phenomena of radioactivity and to its effects on living organisms. Indeed, the effects occurred, but were attributed to other causalities, long before the discovery and description of radioactivity at the end of the nineteenth century. Research with understanding akin to our present ideas is largely a product of the twentieth century, with some exceptions.

The work is considered in four chapters, beginning with radium because it was the first radionuclide to be connected with certainty to extensive biomedical effects (even though polonium, a decay-product of radium, was discovered first and contributed to the effects seen).

The discussion of radium concentrates on the use, metabolism, and effects of ^{226}Ra and its daughter products when taken in by the luminous dial painters, radium chemists, and thousands of patients who received radium as a therapeutic nostrum as well as its intake in food and water. The discussion does not consider the long-standing uses of radium as a source of gamma radiation in medicine or the experiences with large radium sources (primarily for the production of radon) in hospitals. The former is a problem of external radiation and thus not pertinent to our theme. The latter involved primarily occupational exposures to health personnel and, while such sources were widespread, documentation of doses, even incidents, is not sufficient to contribute significantly to the story we are unfolding in these chapters. The more recent experience with ^{224}Ra in Germany is summarized also in chapter 1.

Radium is followed by uranium because of the close association between the two, both physically and in the realization of biological action, though the action of uranium is quite different qualitatively and quantitatively from that of radium. The emphasis is on natural uranium, its behavior and effects, with a short discussion of work done on other isotopes.

The third chapter considers the uranium miner saga and related events attributable largely to the effects of radon gas and its daughter products. For pure antiquity, this discussion should come first, for it goes back to at least the

fifteenth century, but the proof of causality came a little bit later than that for either radium or uranium and so did the peak of research activity.

The section concludes with a short review of biomedical research on polonium and on thorium.^(a) As with the others, their presence and potential biological effects were appreciated early, but the crescendo of research built rather more slowly. Also, these were never a focus for as intense activity in the first five to six decades of the twentieth century as was focused on radium, uranium, and, to a lesser extent, radon plus daughters.

It will be realized, of course, that we are speaking very broadly when we name these elements without further elaboration of atomic weight and number. For convenience, we speak generically of "radium," "uranium," "radon + daughters," "polonium," and "thorium." Actually, these titles, of course, encompass groups of isotopes or whole families of elements. The delineation of the several decay series for naturally occurring radioelements was a major accomplishment of the early radiochemists and physicists. Rutherford described the three major series in his Bakerian Lecture in 1904! In toto, there are many dozens of naturally occurring radioactive elements that were isolated, characterized, and related one to another.

The biological research fixed upon a relatively small number of these. Those that assumed prime importance did so because of their abundance, their energies and half-lives, their effects, or all of these. Hence, we can afford to compress the discussion of the biological effects of these substances, which comprised almost all we knew about radioactivity for many decades, into four chapters of modest length.

Before launching into the biomedical aspects and possible health effects of the naturally occurring radionuclides, we must review briefly the major natural series and the miscellaneous primordial radionuclides. There are many ways of presenting these series. Perhaps the most logical is by plots of the atomic mass (A)^(b) or the neutron number (N)^(c) against the atomic number (Z)^(d). The simplest is by a tabulation as was done by Glasstone in his classical *Sourcebook on Atomic Energy* published in 1950 (Glasstone 1950) and in earlier publications.

A more recent version of such a tabulation with updated values for the constants is given in the *Handbook of Radiological Health*, a most useful document for basic physical aspects of all of our discussions in this book (PHS 1970). The three naturally occurring series, beginning with the most important, uranium, and followed by the only slightly less important thorium series, and finally by the actinium series, are shown in tables PN-1 through 3.

It will be noted that many nuclides emit more than one type of radiation per transformation. Many emit such a predominance of one type that they can be represented as decaying by alpha emission, beta emission, etc., on an N - Z plot (see below). Also, note that there are one or more branches in the chains in each series, but again there is a predominant pathway. Finally, it will be noted that the tables give a column for historical names. These are the names that

(a) The story of the health effects of thorium is far shorter than its importance to chemistry, physics, metallurgy, and industry would predict. The reasons will be clear in chapter 4.

(b) Atomic mass (A) is an integer equal to the number of protons and neutrons in the nucleus.

(c) Neutron number (N) is an integer equal to the number of neutrons in the nucleus.

(d) Atomic number (Z) is an integer equal to the number of protons in the nucleus.

were applied to individual sources of radioactivity as the series were being worked out and before the nuclides and their interrelationships had been conclusively identified. These names are not used currently but are presented here because they appear in some of the older literature that we will reference. A plot of atomic number (Z) against mass number (A) for the uranium series is given in figure PN-1.

FIGURE PN-1. A Z-A plot of the transitions in the uranium series. (Redrawn from Lapp and Andrews 1972. Reprinted with permission of Prentice-Hall, Inc., Englewood Cliffs, New Jersey, copyright 1972.)

On an N-Z plot, the portion of the uranium series beginning with ^{226}Ra looks as shown in figure PN-2.

Note in figure PN-2 that the predominant radiation emitted in the decay determines the change in N and Z and the position on the plot. Thus, alpha decay shows as a diagonal downward to the left, while beta decay shows as a diagonal downward to the right.^(a)

(a) The actual modes of decay are much more complex than this simple description. There are frequently multiple steps. Descriptions of these can be found in the textbook by Lapp and Andrews (1972) and in general treatises on radioactivity.

FIGURE PN-2. A portion of the uranium series on an N-Z plot. (Modified from Lapp and Andrews 1972. Reprinted with permission of Prentice-Hall, Inc., Englewood Cliffs, New Jersey, copyright 1972.)

The thorium and actinium series are shown in figure PN-3, again on N-Z plots. Note in these plots and tables that many of the same elements appear in different series, but as different isotopes, and that all three series have a gaseous member, an isotope of radon. In considering biomedical aspects it is sometimes the whole series that is of importance. In other instances, it is only a portion that is of primary interest. Frequently there is a single isotope of significant half-life and energy that is the nuclide of concern. Hence, we will spend much time on ^{226}Ra , ^{224}Ra , ^{210}Po , etc.

The reader will find in the literature still another scheme for representing one or another of the natural series. This is a plot that usually depicts alpha decay as a downward vertical line and beta decay as a diagonal line slanting upward to the right. This plot is convenient and is frequently shown without any coordinate axes. An example, again for the uranium series, is shown as figure PN-4.

It was long appreciated that there should be a series of the type $(4n+1)$, but no indication of the theoretically possible members was found in nature. It was

FIGURE PN-3. The thorium ($4n$) and actinium ($4n + 3$) series on N-Z plots. The upper Z scale applies to the actinium series only. (Modified from Lapp and Andrews 1972. Reprinted with permission of Prentice-Hall, Inc., Englewood Cliffs, New Jersey, copyright 1972.)

only after its precursors, ^{241}Pu and ^{241}Am , were produced artificially that its existence and composition were worked out. It begins with ^{237}Np , which has a half-life of 2.1×10^6 yr (and is considered important to radioactive waste disposal). It is thus called the neptunium series. This series on a Z-A plot is shown in figure PN-5.

It will be noted that each of the three naturally occurring series begins with a very long half-life member. This has led to speculation that these may represent primordial radionuclide chains and that there may have been others, indeed the earth may once have been much more radioactive than it now is. These other series may have decayed away and disappeared before they could be detected by man.

In addition to the radionuclides in the several series, there are many other naturally occurring radionuclides that do not seem to be members of any series. The only ones of real interest for biomedical consideration are tritium (^3H) with a half-life of 12.3 yr and a weak beta particle emission; ^{14}C with a half-life of 5,730 yr and a slightly stronger, but still weak, beta particle emission; and ^{40}K with a half-life of 1.3×10^9 yr and a combination beta particle electron capture and gamma emission with energy at 1.5 MeV for the latter.

Many of the other naturally-occurring radionuclides discovered also have very long half-lives and, along with ^{40}K , may be considered primordial. Tritium and

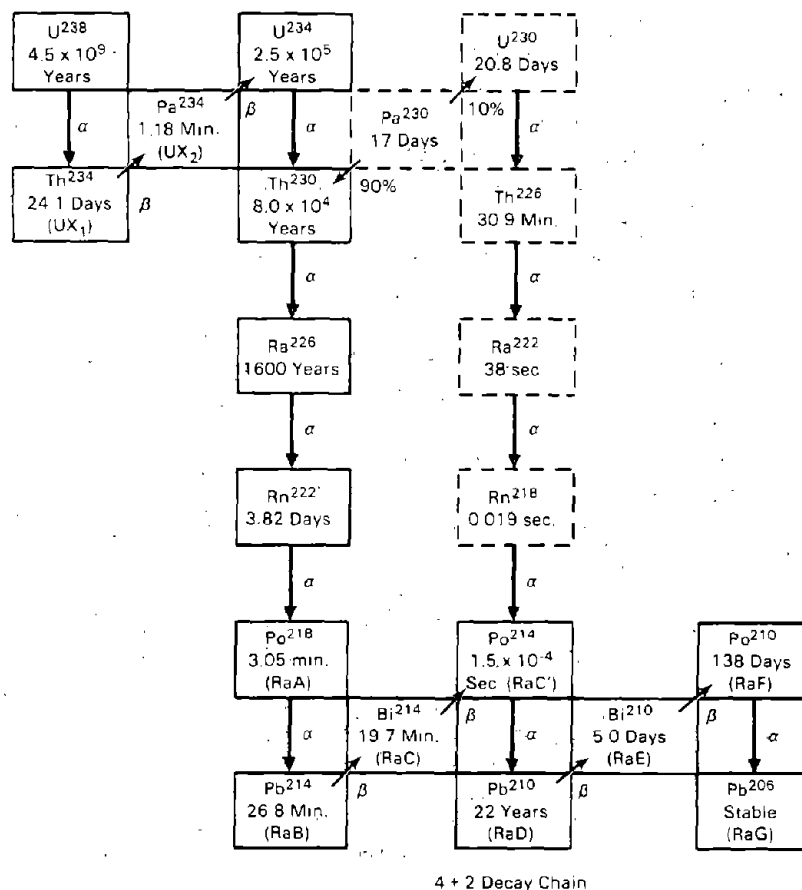

FIGURE PN-4. The uranium series. Note that the series beginning with U^{230} would not occur in nature because of the short half-lives. (Redrawn and modified from Albert 1966, taken from *Thorium Production Technology* by Cuthbert. Reprinted with permission of Addison-Wesley Publishing Co., Inc., Menlo Park, California, copyright 1958.)

^{14}C , by contrast, are constantly renewed by the interaction of cosmic radiation with elements in the atmosphere. Others, such as 7Be and ^{22}Na have such short half-lives that they do not concern us here. A tabulation of the naturally-occurring, "nonseries" radionuclides is shown as table PN-4.

Even though ^{40}K has a low specific activity and comprises only 0.0119% of the earth's potassium, there is so much potassium around that it is estimated to produce the highest mean internal dose rates to the world population from naturally occurring radionuclides. Close seconds are the doses from radon and its decay products inhaled in closed spaces and those from radium and its decay products to the cells lining bone surfaces.^(a)

(a) In this discussion, we are considering only the "internal dose," not the external dose.

FIGURE PN-5. A Z-A plot of the neptunium series. This series did not exist in nature until its precursors were prepared artificially, but it may have existed on earth millions of years ago. Note that the half-lives except for ^{233}U are very short. Neptunium-237 (half-life 2.14×10^6 years) and ^{233}Pa (half-life 27 days) precede ^{233}U . (Redrawn from Lapp and Andrews 1972. Reprinted with permission of Prentice-Hall, Inc., Englewood Cliffs, New Jersey, copyright 1972.)

A complete and satisfying discussion of the sources and magnitudes of naturally occurring radiations can be found in the reports of the United Nations Scientific Committee on the Effects of Atomic Radiation (e.g., UNSCEAR 1977). (See Appendix D for acronyms and abbreviations.)

In toto, the mean annual dose rate from all natural sources is on the order of 100 to 150 mrem and the dose from internal sources is ordinarily considerably less than the dose from external sources. Such a dose is of little biomedical concern, even though it has sometimes been speculated (incorrectly according to most geneticists) that the natural mutation rate in the biosphere might be primarily due to this background radiation rate.

It was when man began extracting the natural radionuclides from their ores and began to prepare more or less pure compounds or to develop mines that

TABLE PN-4. Naturally Occurring, Nonseries Radioactive Nuclei

Symbol	Nucleus			Percent Abundance	Half-life (years)	Emission	Transition energy (Q)

opened up active sources of radon that troubles from biomedical effects began in earnest. Radium as a component of luminous paint or as a therapeutic nostrum is a typical example. Hard-rock and uranium mining is another. Hence, in these chapters we, in essence, consider the history of the biomedical effects of substances that occur naturally, but that were frequently in more concentrated form than in nature at the time of exposure.

It has become popular in recent years to make a distinction between "natural" and "technologically enhanced" sources of some of the naturally occurring radionuclides. We will have occasion to use this distinction in the chapters considering the environment. In this section, we review the radioelements in the form used at the time of the exposures. On the whole, they have all been "enhanced" to a greater or lesser degree. It is the fact that they originally occurred naturally, i.e., they were not created artificially, and the effects were, in general, first noted before the creation of artificial radioactivity that places them in this section.

For continuity, the work with these radionuclides done over many decades is summarized in each chapter. This includes the period prior to World War II, the work done during the years of the Manhattan Project (Manhattan Engineer District), and in the decades since World War II to the late 1970s or early 1980s. In

later years, the sources may have sometimes included "artificial" modes of generation (for example, the preparation of ^{210}Po); but the properties of the isotopes are identical whether the source was the original natural source or a later artificial process.

For convenience, and again for continuity, most research involving inhalation exposures has been gathered into chapters 9 and 10. This includes the naturally occurring radionuclides. Thus, the chapter on uranium in this section (chapter 2) is considerably shorter than it would have been had all of the enormous efforts on its inhalation toxicology been included. On the other hand, because of its direct bearing on the carcinogenic potential of uranium under long-term exposure conditions, one inhalation experiment, a large one, is included in chapter 2.

The work on radium is continuing, but at a slower pace and with special emphasis on completion of studies on persons exposed many decades ago. This must be done, or much of the epidemiologic value of decades of work will be lost.

Uranium has not commanded the research attention it once got except for waste disposal problems and a belated, but laudable, attempt to mount a formal epidemiologic study of uranium workers. Nevertheless, uranium continues to consume much time and many resources in the realm of industrial operations and regulations.

The most active area at present among these naturally occurring radionuclides concerns radon and its daughter products. The emphasis has shifted away from the uranium mines because of improvements in ventilation (except for continuing litigations regarding past exposures) to exposure of the public. The trend to tighter buildings, for energy conservation, with less air exchange and some unfortunate mistakes in the use of contaminated mill tailings in building materials sparked many investigations in homes and public buildings. The results indicate that radon and its daughters may contribute, even in ordinary buildings, the highest radiation dose to the population of any of the naturally occurring radioelements,^(a) indeed, of all of the radionuclides that deposit in the body under ordinary conditions. Its significance will be discussed at the proper place.

Work on thorium is continuing in the form of epidemiology and continuing efforts to establish true causality in the cases where Thorotrast (a radiopaque dye—see chapter 4) was used. Continuing biomedical work with polonium has been minimal except for attempts to link its presence in cigarette smoke to the development of lung cancer in smokers.

As indicated in the general preface, emphasis has had to be placed in this book on work done in the United States. However, so much of the early basic work on natural radioactivity was done in other countries that these chapters can have more of an international flavor than some other sections of the book.

(a) Radon vies with ^{40}K for this "honor" in populations living in closed dwellings and sometimes wins. In terms of world population, it is not number one because of the large portion of the world population living in open dwellings. Thus, the dose from radon and its daughter products is much more variable than that from ^{40}K . As noted in chapter 4, the tobacco smoker gets a large additional dose from ^{210}Po - ^{210}Pb , but we will not view this as "normal background" radiation to the world population. Recent surveys indicate an additional and sometimes large concentration from the ^{210}Po - ^{210}Pb in foods. These frequently exceed both ^{40}K and radon plus daughters.

Even though current biomedical work with the naturally occurring radionuclides is not today at the almost frenetic pace of some of the earlier decades of this century much continues to be and should be done. In retrospect, we must conclude that the researches on biomedical aspects of naturally occurring radionuclides laid the foundation for the entire field. They continue to make important contributions. The amount that was learned in the early decades, despite crude instrumentation and methodologies that would not be tolerated now because they are too laborious, cannot help but generate much admiration for the scientists and physicians involved.

Capsule Chronology^(a)

- 1898 Radium-226 isolated from pitchblende by M. Curie.
- 1898 Becquerel receives skin burn from radium carried in his vest pocket.
- 1902 Radium-224 (thorium X) discovered by Soddy and Rutherford.
- 1910 Curie unit defined as activity of 1 g of radium.
- 1910 et seq. Animal work on distribution and excretion of radium (mostly in Europe). Beginning of use of radium as a therapeutic nostrum.
- 1912 Arthritis patient dies because of ^{224}Ra injections.
- World War I Exposure of hundreds of girls to luminous paint compound used for painting numerals on military instruments.
- 1920 et seq. Luminous dial painting expanded to clock factories.
Radium chemists.
Uses of radium by injection and ingestion for treatment of numerous real and fancied disorders increase to thousands of patients throughout decade of the 1920s.
- 1922-1924 Suspicions develop around dial painters' jaw lesions.
- 1924 Description of jaw necrosis by dentist, Blum; attributed to radiation from deposited luminous paint.
- 1925 Physician, Martland, describes pathology of bone changes and anemias in dial painters.
Hoffman decides the dial painters' cases represent a new type of occupational poisoning. Attributes it to mesothorium in dial paint.
- 1925-1929 The saga of dial painters and iatrogenic cases unfolds.
- 1929 Osteogenic sarcoma proven in the dial-painter population. (Reported but not proven to be causally related in 1924 and 1927.)
- 1929, 1930, Collaborative work by Schlundt (Missouri), Failla (Columbia), and
1931, 1933 others on radium metabolism in patients at Elgin State Hospital in Illinois. Patients had received radium as therapeutic nostrum.
- 1931 "Alpha particles are probably the most potent and destructive agent known to science" (Martland).
- 1932 Eben Byers, prominent Pennsylvania industrialist, dies of the effects of drinking "Radithor." Other cases begin to follow. Robley Evans is put on the radium trail by Robert Millikan, and thus begins a brilliant and productive career that continues to this day.
- 1933 First effort to reduce radium body burden by manipulation of diet and administration of parathyroid hormone.

(a) These abbreviated chronologies were prepared as a service to the reader who may wish easy access to the general progression of events or to find a single date. In general, they focus on items described in the text of the pertinent chapters. In some instances, events are listed that could not be included in the text because of space limitations. Also, certain events were pertinent to several chapters. In such cases, the same event is not repeated in several listings unless it has key significance to the subject at hand.

1934 et seq. Principles and practices of in-vivo counting of radium initiated by Evans at MIT.^(a) Continues at MIT until work moves to Argonne National Laboratory in 1970, where it is still continuing; the first "whole-body" counting.

Also much work on the ratio of radon in expired air to radium in the body.

1934-1939 Measurements begun on radium content of natural waters.

1936-1941 More animal work on distribution and excretion and effects of radium and its decay chain products; some of it at MIT. Rat much more resistant to chronic effects of radium than man and not considered a good model.

1941 Standard for radium is promulgated in terms of maximum allowable body burden ($0.1 \mu\text{Ci}$); has held up for decades (see chapter 16). It protected workers during the large expansion of luminous dial painting during World War II.

WORLD WAR II

1941-1947 Examination and measurement of dial painters and patients continues at MIT despite the pressures of war work.

Animal work under the Metallurgical Laboratory (Chicago), partly as "base line" for work with fission products and actinides.

Norris and colleagues demonstrate retention is best described by a power function of time (still referred to as the Norris equation). Soft tissue distributions revealed in depth. Acute toxicity of radium studied in animals. Unique calcification seen in blood vessels and soft tissues. Work on late effects in mice begun by M. Finkel.

Animal work at University of Rochester: distribution and excretion of radium, acute toxicity in the rat, hematology, pathology. Comparative toxicity to plutonium and polonium (Bale, Boyd, Fink, Casarett, and colleagues). Calcification of blood vessels also seen.

POST-WORLD WAR II

1947-1970 Work with dial painters and patients resumes at MIT and increases markedly.

New populations found and added. Dose-response functions determined, idea of practical threshold deduced; osteosarcomas multiply. Carcinoma of the sinuses appears.

1948 Heinz Spiess asked to investigate ^{224}Ra therapy cases in Germany.

1950s Work begins at Rochester (Hursh et al.) on natural radium content of body and of water.

Rochester work on radium during war published as part of National Nuclear Energy Series (Fink).

Role of mesothorium worked out.

Work on man and animals continues at Argonne National Laboratory with special emphasis on patients at Elgin State Hospital.

(a) For abbreviations and acronyms, see Appendix D.

Radium is introduced into the Utah and Davis beagle studies (see chapter 8).

Work at Argonne National Laboratory on areas with high radium content in drinking water.

- Late 1950s through 1960s** "Argonne Radium Studies" (A. Finkel, R. Hasterlik, C. Miller, and others) using new population of dial painters found in Ottawa and La Salle-Peru, Illinois (Argonne National Laboratory and Argonne Cancer Research Hospital).
- 1950s-1970** Large-scale program at Argonne National Laboratory on relative toxicity of radium to many other bone-seeking radionuclides in mice (M. Finkel and colleagues). See chapter 8.
- 1952** Follow-up of ^{224}Ra cases begins.
- 1953** Argonne Cancer Research Hospital opens.
- 1963** Radium-224 added to the Utah beagle experiment.
- 1969** Mays, University of Utah, begins collaborative work with Spiess in Germany on ^{224}Ra cases.
- 1970** Radium work in man consolidated at Argonne National Laboratory in new "Center for Human Radiobiology" with a field station remaining at MIT and a new one in Scottsdale, Arizona, Evans's retirement site.
- Exhumation program continues through all offices.
- Concentration on dose-response functions.
- 1975 et seq.** Follow-up reports on radium patients and female dial workers from Center for Human Radiobiology. Effects and dose-response relationships.
- 1979** Radium-224 cases sufficient for definitive summary.

Chapter 1

First It Was Radium

Overview

This chapter gives a much more extensive coverage of its subject than merely the events between the late 1930s and the mid-1970s as was our original intent. The story of the radium dial painters, chemists, and the nasty surprises that radium brought upon the scene was, I thought, common knowledge among most of the intended readers of this book. But inquiry, both direct and indirect, established that this was not the case, especially among the younger investigators and potential managers who are considered prime targets for this book. Nor was it clear that the extensive past documentation would be read if this chapter began with only a collection of references.

Therefore, at the risk of boring a few readers, I decided to try to cover the whole story to some degree.

The title "First It Was Radium" might be expanded to "First It Was Radium And It Continues To Be." The radium experience has provided the bulk of the original findings on the long-term effects of radioisotopes in the body (internal emitters) and the best source of such information on humans. It continues to provide essential information and, if the projects are continued as they must be, the collection will continue until well into the twenty-first century.

On this basis, the chapter on radium attempts to cover as much of the pertinent research and ideas behind the research as could be mustered without undue length and unnecessary detail. Since the radium saga is basic to all of our other considerations, it is hoped the reader will persevere and find it as fascinating as the author has over the years.

I. Introduction

Why should a book concerned nominally with the organized research on radioisotope (i.e., "internal emitter") toxicology from the 1940s into the 1980s reach back to the end of the nineteenth century to discuss work done so many years ago?

It is because the first extensive experience with the untoward effects of radioisotopes was with radium and its first decay product, ^{222}Rn . It is because the biomedical effects of radium were center stage for much of the earlier twentieth-century work with radionuclides and because experience with radium

has provided the best, most complete, and most reliable information on long-term effects of deposited radionuclides in man. Radium-226 and now some of its shorter-lived cousins continue to supply important bench-mark information. Also, experience with radium provides a total of recorded cases of significant exposure to long-lived radionuclides that exceeds all others. Even the close competitor, exposure to radon and its daughters in mining operations, has not provided as many well-studied and well-documented cases as radium, even though the total numbers of individuals exposed may exceed several fold the total of the radium cases. (The problems of the uranium and other miners will be taken up in chapter 3.)

Was radium really first? It was not in terms of announced discovery. The radioactivity of uranium was announced by Becquerel in 1896 (Becquerel 1896a,b;c, d,e,f). Polonium was the first highly radioactive element separated from pitchblende by the Curies. This was announced on July 18, 1898 (Curie and Curie 1898). The separation of radium waited until December 26 of the same year (Curie, Curie, and Bémont 1898). But in terms of biological effects, ^{226}Ra easily occupies the position of "first" both chronologically and in importance.

The early decades have been extensively documented and provide a chronology second to none in the history of radioisotope toxicology. Nevertheless, we cannot deny ourselves the opportunity to look again, albeit hastily, at that saga. Furthermore, the effort continued throughout the years of World War II and with renewed vigor in the 1960s and 1970s, the periods of most concern to this review. It will continue in the 1980s. The following pages will review first the highlights of the early decades. Then we will look in more detail at the more recent efforts and thereby at some of the biomedical problems still remaining to be solved.

II. The Early Decades

The five years between 1895 and the start of the twentieth century were indeed a remarkable period for radiation science. Beginning with Roentgen's announcement of x rays in 1895 and Becquerel's finding of the radioactivity of uranium in 1896, the period saw in rapid succession the separation of polonium and radium (Curie and Curie 1898; Curie, Curie, and Bémont 1898). Then came the discovery of the radioactivity of thorium announced by Schmidt in 1898, and Marie Curie indicated that thorium ores could be more radioactive than uranium. Further, it was appreciated that these elements had numerous progeny ("daughters") that were also radioactive.

Most of these early activities took place in France and Germany, but they were not alone. In England, J. J. Thomson and his young graduate student Ernest Rutherford were, among others, busy establishing the fundamental physics of "ionization" (Faraday's term). Rutherford established that the radiations emitted by uranium were of two types, alpha and beta he called them. He established the basic properties of and differences between them,^(a) partly after he moved to McGill University in Montreal, Canada.

If it had not been for Irène Curie (as Brucer aptly put it in 1979),^(b) the chronology of the early discoveries in radiation science might have been even more

(a) Others cite Pierre Curie as doing this separation and classification in 1900.

(b) American research on radioactivity in the early twentieth century is beautifully summarized and analyzed in a recent book by Badash (1979).

closely packed. It was hardly Irène Curie's fault, but her gestation period happened to come right in the period of feverish efforts by her mother to separate out the unknown sources of radiation coming from uranium ore. In retrospect, it may have been just as well that her fetal development took place before her mother had been unduly exposed to radiation as she undoubtedly was as the work progressed. For, as we shall see in chapter 5, Irène Curie followed fittingly in her mother's footsteps and brought forth, with her husband Frédéric Joliot, the first artificially produced radioisotopes.

The biological effects of radiations from radioisotopes were not long in coming to light. During the first months after the announcement of the properties of uranium and radium, Becquerel is reported to have carried a small vial of radium, obtained from Madam Curie, in his vest pocket in order to demonstrate its remarkable properties on short notice. It is further reported that Becquerel turned up with a classic erythema (from a radiation burn) on the skin next to his vest pocket. This was, of course, an effect of the penetrating radiation from the radium. It was *not* an effect of a radioisotope deposited within the body. But we can put it down as the first recorded effect of the radiations from radium.

The history of the discovery of biomedical effects of *deposited* radionuclides is quite different from that of x rays and external radiation sources in general. It was less than a year from the beginning of the general use of x rays that untoward biological effects were recognized. The better part of two decades passed before similar appreciation came regarding radionuclides deposited in the body. This situation was due in part to the relatively fewer chances for exposure because the sources were usually encapsulated, and only their penetrating radiations were employed in medicine. It also reflects one of the most characteristic features of internal emitter toxicology. Except for occasional large exposures, we are dealing with effects that have years of latency before the end result becomes apparent, "the slow burn" in modern parlance. In addition, there seems to have been something of a blind spot in the thinking of those years, and the possibility of catastrophic long-term effects of deposited radionuclides, especially alpha emitters, seems not to have been brought into focus. There was animal work from about 1910 on the distribution and excretion of radium (see bibliography by Schwind and Croxton 1950). But it was into the post-World-War-I years before the biomedical effects came suddenly to light, and the toxicity of radium in the body became fully apparent. And the results are still accumulating (1980s)!

III. Luminous Dial Painters, Radium Patients, etc.: The First Decade of Enlightenment

As Eisenbud (1979) remarked, an extraordinary series of coincidences, plus some prepared minds, resulted in a sudden and rude awakening to the effects of alpha emitters deposited in the body. It began in 1924 with a perceptive dentist (Blum), followed quickly by a conscientious and talented physician and pathologist (Martland), a chemist (Gettler), another perceptive physician (Hoffman), and later a remarkable series of measurements, analyses, and interpretations by a capable and broad-gauged physicist (Evanis).

The prodromal signs were already present in what was termed at the time "professional anemias," which occurred in radiologists and others using x rays

and radioactive materials in medicine (Martland, Conlon, and Knaf 1925, p. 1786). But the fat was not fully in the fire until a New York dentist, Theodore Blum, mentioned an entity he termed "radium jaw" in a three-line footnote to a paper given before the American Dental Association on osteomyelitis of the jaw (Blum 1924). Blum was impressed by the unusual and intractable nature of the osteomyelitis in a girl from New Jersey who worked in a dial-painting plant. Other cases of jaw necrosis were being seen by other dentists.

In 1925, F. L. Hoffman was called to the plant by the New Jersey Consumers' League.^(a) He was impressed by the similarity of the death certificates of deceased former employees and decided that they represented a new type of occupational poisoning. He attributed it to mesothorium in the luminous dial paint (Hoffman 1925). This report was followed very shortly by the paper by Martland and colleagues already cited. Martland was with the medical service of St. Mary's Hospital, Orange, New Jersey, the pathology department of City Hospital, Newark, New Jersey, and was, in addition, in the office of the county physician of Essex County.

The picture was one of acute necrosis of the jaw, usually involving infection and severe leukopenia and anemia, occurring from one to seven years after the patients terminated work as dial painters. (Many of the young women worked at dial painting during World War I.) These are what would now be characterized as "early cases" (Martland 1929). The causative agents were identified as ^{226}Ra , and/or mesothorium, primarily mesothorium I, an isotope of ^{228}Ra , with a leaning toward implicating the latter.

There were, of course, the usual protestations of innocence on the part of the company. It was not the paint but something else, even syphilis. Even some quite sincere physician-investigators, e.g., F. B. Flinn, required three or more reports, each one incorporating new evidence, to be fully convinced.^(b) (Perhaps this was because Flinn was seeing women from the watch- and clock-making plants in Connecticut, and the paint did not have the same composition there.)

The factory executives commissioned their own investigation as to whether or not any occupational hazard existed. A report was prepared by W. B. Castle, Katherine R. Drinker, and Cecil K. Drinker of Harvard University in March 1924 (Castle, Drinker, and Drinker 1925). It seems not to have been at variance with the Martland or Hoffman reports in implicating alpha radiation from deposited radium, but it was delayed in publication at the request of the company because of threatened litigation and also to give time to check up on evidence for possible zinc poisoning and the possible role of general hygiene in the plants.

The first patients examined carefully enough to provide full details, including autopsy samples for both pathological and radiochemical analysis, were those

(a) This was part of an organization, the National Consumer's League, that has a venerable history of crusading for causes of worker health and rights. Erma Angevine (1979) has prepared a definitive history of the League. Among those active on the dial painters' behalf was Florence Kelley, a protégé of Alice Hamilton, whose efforts have been described recently by Roger Cloutier (1979, 1980). Both of these papers introduce the sociological and economic aspects of many of the events that we will review in this book from the standpoint of scientific research and discussion of which we must forego in order to tell the scientific and technical history.

(b) The completeness of Flinn's conversion to the view that radium was the culprit is attested to in a later paper, "Stimulating Action of Radioactive Deposits in the Body," published in 1934 (Flinn 1934).

reported by Martland (1925). In inexorable progression the saga unfolded. Probably the clearest, most-detailed presentation of both historical order and medical characterization can be found in Martland's later review paper (Martland 1929). The fact that a new occupational hazard was upon us was gradually accepted. Indeed the dial-painting plants were modified and cleaned up, and the practice of tipping the brush between the lips was prohibited so that further exposures from this source probably ceased by the late 1920s. Some put the date as early as 1926.

Cases showing less serious effects began to appear. These presented a somewhat different clinical picture, less necrosis, less anemia, less disability. It was thought that these individuals had less total body burden or the mesothorium had decayed away (5.7 years half-time) without exerting its effect as fully as in cases with more mesothorium. The anemia, if it persisted, was of the regenerative type. Toward the end of 1928, Martland hoped that the worst period, at least for the New Jersey cases, was over.

But it was, as Martland states, "an insidious lull." By the end of 1929, cases of osteogenic sarcoma began to appear, with the death of one young woman.^(a) Pathologic fractures began to appear also, and it was clear that a second, more insidious, but just as serious, stage had begun. Actually, bone sarcomas were reported from two cases dying in 1924 and 1927 (Martland and Humphries 1929), and these led Martland to suspect that there would be more to come. Indeed, he stated in 1929 that in 1925 he made a list of fifty out of the eight hundred or so women employed at the New Jersey plant most likely to show symptoms using length of employment as the criterion. "With terrible, almost mathematical regularity, I have been crossing off these names as the girls have died or developed symptoms of radium poisoning."

The late cases had many differences from the early ones. These differences included in some cases fairly long periods of reasonably good health that continued up to a few months before appearance of the terminal cancer. Also, there were many puzzling exceptions noted, including some differences occasioned, it would appear, by differences in the paint at different times and at different plants. Many of these will be examined when we look at the more analytical decades to follow in later sections.

Despite the furor stirred up by the luminous dial painter cases, exposure to radium continued to occur elsewhere during all of the 1920s. Chemists, physicists, and physicians working with radium were among those fatally exposed. The chemist who mixed the paint for the New Jersey plant, doing it only himself because it was a trade secret, was one of them. But they were a heterogeneous group scattered about the country and did not attract the kind of attention a group of eight hundred girls and women could.^(b) Also, practitioners of medicine continued to give injections of radium for its "stimulative action."^(c) Many

(a) She was one of five who had been given an out-of-court settlement for their disabilities, inadequate of course, and the press picked up the issue under the rubric of *The Five Women Doomed to Die*.

(b) There were many other dial-painting plants and some hundreds of other dial painters, but their story took much longer to unfold. In fact, the more complete version has had to wait until the post-World-War-II years, as we shall see later in this chapter.

(c) These are termed in the literature "iatrogenic" (Greek, *iatros*, physician + -GENIC for generated). One wonders what therapy is now in use that will have effects that some future generation will label "iatrogenic."

patients drank radium water or a patent nostrum called "Radithor," sometimes in quantities that stimulate admiration for the resiliency of the human machine. The harvest was slower to be reaped (or was it slower to be recognized?) in these cases than in the worst of the dial-painter cases.

IV. The Decade of the 1930s: Quantitation, Therapy, and Metabolism

A. The Transition

While the publications on radium in humans in the 1920s were laced with discussions of possible mechanisms of the pathologic changes seen, some of them very complete (e.g., Martland 1929), the primary lesson of the decade of the 1920s might be summed up in Martland's conclusion: "Alpha particles are probably the most potent and destructive agent known to science." There had been pioneering research efforts on retention and distribution, e.g., as a function of route of administration (Seil, Viol, and Gordon 1915; see also survey by Silberstein 1945, 1950a; and bibliography by Schwind and Croxton 1950), and some quite prescient discussions of how radium is metabolized, i.e., like calcium and like lead. Nevertheless, the latter part of the 1920s and the decade of the 1930s, up to the time of our entry into World War II, saw a marked increase in such investigations. These were aimed primarily at quantifying the radium burden of people exposed in earlier years, at establishing the kinetics of distribution in and clearance from the body, and, in general, getting at the mechanisms behind the events established in the 1920s.

Since the decade of the 1930s saw the beginning of the work of Robley D. Evans, who has been, and is, a towering figure in the field of radium toxicology (indeed all of radiation toxicology), we might well start with his introduction to the field. Evans is a physicist with profound interest in and understanding of biology. Throughout his career, he has been part of singularly symbiotic associations of physicians, dentists, physicists, chemists, biologists, even epidemiologists, where no one lost his identity, but the whole has been much more than the sum of its parts. The way he got "invited" into the radium field is interesting and worth repeating, for he was doing Simon-pure physics and geophysics at the time, related to radioactivity from natural sources.

In 1932, a prominent Pennsylvania business tycoon named Eben Byers, president of Byers Steel, died from the effects of slavish devotion to the nostrum "Radithor." Radithor was certified to contain 1 μCi of ^{226}Ra and 1 μCi of ^{228}Ra (radiothorium) per half-ounce bottle. Mr. Byers had devotedly taken four bottles per day for a considerable period! It perhaps did have the often described initial stimulatory effect of radiation and radium, but it brought Mr. Byers down with classic radium poisoning.^(a)

Perhaps it was because Mr. Byers was National Amateur Golf Champion, as well as a very popular bachelor and well-known industrialist, but, for whatever

(a) Only the well-to-do could afford four bottles of Radithor per day. It took somewhat longer for ordinary folks, but they got there just the same. The number of persons who took radium in one form or another on either their own initiative or through their physicians will never be known accurately. But the total is bound to be in the thousands.

reason, his death brought spreads in the national press, including a relatively new magazine called *Time* (Evans 1978a). The Los Angeles County Health Department recoiled at the idea that such things might happen in California. They sent an emissary to Robert Millikan, well-known physicist at Cal Tech, and Evans's boss and thesis advisor. Millikan brought the representative (a Dr. Crandall) to Evans with some remarks to the effect that here was a man interested in radium and left him with the remark, "you do what this man tells you." Thus, by a fortunate accident began one of the longest and most productive careers in American radiation science and the toxicology of deposited radionuclides.

The first tangible result of this assignment was a paper by Evans before the American Public Health Association, published in 1933, by which time Evans had become a National Research Council Fellow at the University of California, Berkeley (Evans 1933). The paper is a carefully structured review of the work already done, some of it only begun, and it presaged many areas that were to occupy his attention and that of many others in the years to come.^(a)

B. Measurement In Vivo

A central theme of Evans's work, and much of that in the period, was the quantitative measurement of body burden of radium and related nuclides in living individuals. The work in the 1920s included measurements of expired radon and thoron, more as a clue to whether or not a given case had a significant burden than as a quantitative measure. Also, measurements were made by placing electroscopes near the individual and also by analysis of feces. (Since exposure was largely by ingestion, urinary excretion was negligible.) The results were far from satisfactorily quantitative. Evans began studies on the metabolism of radium in patients in 1933 (Evans 1978b). However, the primary thrust toward measurements in vivo awaited his joining the faculty of the Massachusetts Institute of Technology (MIT) in 1934.

The techniques developed at MIT used Geiger-Müller counters (gamma-ray quantum counters) to measure the relatively feeble gamma emissions from deposited radium C in the human body (Evans 1937). They differed from earlier measurements that used gamma-ray electroscopes and which required obtaining autopsy samples of bone for calibration (see Schlundt, Barker, and Flinn 1929; Barker and Schlundt 1930). They were susceptible to internal calibration by a method known as the "Meter Arc Calibration Technique." The principle is that the patient is located so that all portions of his body lie on an arc with a 1-m radius to the detector, which is at the center. By measuring with the patient first facing the detector, then with the back toward the detector, remeasuring with known radium standards placed behind the shoulders, hips, and knees, and finally measuring with only the standards present, a calibration could be made. Not many patients were subjected to this time-consuming process, and some had to be along a 1.5-m rather than a 1-m arc. But the procedure gave calibration points so that routine measurements could be made away from the laboratory with the patient seated in a chair, and the detector could "look at" eleven points 1 m away.

(a) In Evans's case, these were side by side with continued work in physics, instrumentation, and geophysics, and a major text on the atomic nucleus.

This was essentially the beginning of whole-body counting, and it happened in the early 1930s!

The technique was supplemented by analyses of expired radon. This procedure was carried out for two purposes: (1) Many patients and workers could not be brought to the laboratory, but breath samples could be collected and measured, and (2) calculations of radiation dose depended critically upon quantitation of the fractional loss of radon from individuals bearing a measured radium burden.

With gradually increased sensitivity and sophistication of instrumentation, the measurement of the gamma emissions from deposited radium continued for a variety of individuals grouped under the general heading, "The MIT Cases," or sometimes the "MIT-MGH Cases." In the earlier days, those measured were primarily those referred by physicians to the Massachusetts General Hospital (MGH) or perhaps directly to the laboratory because they either had symptoms, or they themselves suspected they had a body burden of radium or luminous dial compounds. Later the investigators began to seek out individuals expected from the records to be bearing radium or luminous compounds. Indeed, it is reported that a private detective was hired at one point in the study to help trace down some of the dial painters who had married, moved many times, and might or might not place any importance on their period of employment as a dial painter.^(a)

Concurrent with the developments at MIT-MGH was a collaborative effort by Herman Schlundt, a physical chemist at the University of Missouri; Howard H. Barker of the U.S. Radium Corporation; Frederick B. Flinn, M.D., a professor at the Institute of Public Health at Columbia University; G. Failla, a radiological physicist at Columbia; and later, John T. Nerancy, M.D., Clinical Director at the Elgin State Hospital, Elgin, Illinois. In a series of papers under the general title, "Detection and Estimation of Radium in Living Persons," these workers wrote first about the methods themselves (Schlundt, Barker, and Flinn 1929), the estimates of body content of ten patients treated with radium (Barker and Schlundt 1930), the normal elimination of radium from living persons (Schlundt and Failla 1931), and the first reports from the Elgin State Hospital group of patients (Schlundt, Nerancy, and Morris 1933). This research centered primarily on measurements of amounts present and the "metabolism" of radium rather than upon effects. It is notable, in part, for uncovering the relatively large and stable group of cases given radium injections iatrogenically in the Elgin State Hospital. But the primary contributions of these cases had to await the Argonne Radium Studies begun in the early 1950s. (See post-World-War-II work.)

(a) Exaggerated and totally incorrect rumors seem to have dogged radiation science from the earliest days. One such refers to Evans's measurements of the radium burden. Dr. Samuel Lind, one-time president of the American Chemical Society, spent much of his professional career on the properties of alpha-particle-emitting elements. Suspecting that he might be carrying a significant body burden, he checked in at Evans's laboratory to be measured. Later he partook of a friendly dinner at the Evans's house. Much later, a rumor appeared that Evans had surreptitiously placed a gamma-ray counter under Lind's chair at the dinner table and had the counting equipment set up in the kitchen. Evans's frequent trips to the kitchen were put down as trips to take readings. Totally untrue! No one knows how the story got started. Having also had dinner at the Evans's home, I suspect his frequent trips to the kitchen were to refill his guests' wine glasses, or otherwise see to their needs.

There were studies and measurements of dial painters in England and in Switzerland where farm wives did dial painting during the winter months. Also in this period there grew a sizeable French literature, primarily on metabolism and effects, but well quantified; and much work was done in Germany, particularly in the laboratories of Rajewsky and Krebs (see Silberstein 1945, 1950a). Some of these will be cited in other connections. Others must be omitted.

On balance, it was the MIT-MGH group that kept consistently and systematically at the business of measuring radium body burdens during the 1930s. And in those days, it was primarily radium rather than mesothorium that could be measured *in vivo*. It was slow work, however. By the early 1940s, a total of twenty-seven cases had been studied in enough detail to be the basis for the radium exposure standard, which will be taken up in chapter 16.

C. Approaches to Therapy

The gradual realization that there were many hundreds of human beings with body burdens of radium and luminous paint compound that portended serious illness in their later years naturally led to investigation into possible means to remove the deposited radium. A process of "deleading" patients suffering from lead poisoning was proposed by Aub et al. at MGH in 1926 (see Aub et al. 1926). Since lead acted much like calcium, and radium was metabolized much like calcium, it was decided to try to influence first lead and then radium with agents that affected calcium metabolism and by manipulation of calcium intake in the diet. These were the days when "viosterol," a vitamin D preparation, was used in large quantities. It was, of course, a logical candidate for possible therapy because of the important role of vitamin D in calcium metabolism. Another candidate was parathyroid extract (Hunter and Aub 1927).

The pioneering work toward therapy of radium poisoning was done by Flinn and Seidlin (1929) using parathyroid hormone and by Flinn (1931) using viosterol. Later, Craver and Schlundt (1935) introduced low- and high-calcium diets along with parathyroid hormone (extract) and viosterol. There seemed to be some increase of radium excretion with low-calcium diet plus parathyroid extract, but there was no substantial reduction of the total amount of radium in the body.

The MIT-MGH group joined the activity with a study of three patients (Aub et al. 1938). They used manipulation of calcium intake and parathyroid extracts and other measures such as ammonium chloride, magnesium gluconate, and thyroid extract. The quantities of radium mobilized were enough to increase elimination significantly (excreta were routinely collected and analyzed in this work), but the effect on total body burden of radium was still small. Yet, in one case, there was marked clinical improvement, particularly of the jaw symptoms and roentgenographic changes.

On the whole, it appears that these forays into therapy did more to enhance knowledge of radium metabolism than to provide a truly effective therapeutic tool. It is not surprising that mobilization of large amounts of radium did not occur. Experience in later work with a variety of nuclides to be discussed in chapter 19 indicates that the heavy metals once fixed in bone are difficult to remove, and even when removed from bone may still be difficult to transfer from blood to excreta. Also, there are strict limitations on what can be done without risking serious imbalances of calcium metabolism because calcium seems to be more mobile than the heavy metals.

The number of cases studied was of course small. The facilities of a fully equipped metabolism ward were needed, and the work was expensive and demanding. Whether due to differences in the state of radium in the body or other factors, the results were quantitatively quite disparate. This fact, plus the small number of cases studied, left for posterity an equivocal story that rates "A" for effort but which did not encourage further large investments of time, manpower, and money.^(a)

D. Distribution, Excretion, and Retention of Radium

Definitive information on the "metabolism" of radium was slower in coming than the clinical findings and the facts of radium poisoning. This situation was due in large part to the fact that the actual intake was not quantified except in retrospect by the work from the Schlundt group and the Evans group already described. Good metabolism studies require a reasonable knowledge of the initial dose and the initial body burden upon which subsequent behavior can be based. The bibliographies by Silberstein (1945, 1950a) and by Schwind and Croxton (1950) contain references to deposition in animals, including horses, as far back as 1910 and in humans during the 1920s, e.g., Schlundt, Barker, and Flinn (1929), but satisfactorily quantitative work began in earnest during the 1930s. Information from humans and from rats appeared almost simultaneously in 1933. Schlundt, Nerancy, and Morris (1933) utilized the group of patients at the Elgin State Hospital, Elgin, Illinois. These patients received weekly doses of about 10 μg of ^{226}Ra over periods of two to ten months in 1931. The doses were intravenous and reasonably well known except for the ubiquitous problem of adherence of the nuclide to the inside of syringes, bottles, etc. They were given as something of a last spurt in the use of radium injections for therapy in reputable medical institutions. The authors measured exhaled radon and gamma-ray emission from the patient's back.

Thomas and Bruner (1933) gave ten albino rats injections of 5 μg at irregular intervals. While the main thrust of their study was to check effects for comparison with those seen in the dial painters (they were qualitatively similar except for the anemias), they analyzed the residual carcasses of eight experimental animals with considerable care.

The results of both these studies and others (see summaries already cited) showed that radium was eliminated fairly rapidly after entry into the body, with elimination largely via the feces. There was deposition initially in many soft tissues including kidney, liver, spleen, and bone marrow, but retention was short in these, whereas bone accumulated larger and larger fractions with time. Thus, for consideration of long-term effects, it could be assumed that 90% or more of the radium was in the skeleton. (There was an effect of route of administration, however, with much less remaining in bone after intradermal administration [Silberstein 1950a]). Furthermore, the skeletal distribution itself was far from uniform. Different bones concentrated different amounts, and within a given bone there were marked differences. In general, the growing epiphyses localized radium rather specifically, perhaps in part because of their rich blood supply and in part because new bone growth was occurring there. But at later

(a) It is puzzling, however, that radium seems not to have been a prime candidate for study when the various chelating agents came along in later years (see discussion in chapter 19).

times, the radium was seen to migrate into the mineral phases—presumably by exchange for calcium. In this form, the radium is most difficult to remove, which may account for the poor results of attempts at therapy. Thus, although only a small fraction of the initial dose was retained, that fraction was very firmly bound, and retention half-times of forty years or more were estimated even in these early studies. Finally, it appeared that oral doses were eliminated more readily and more completely than parenteral doses.

Details of the metabolism of radium in humans and animals have occupied the attention of investigators ever since. We will have occasion to look again at this subject as we examine the work of later years. We should pause, however, to note that even this early work was quite useful, and in some respects it set the stage for much of the work on retention, distribution, and excretion, which became central themes of the internal emitter toxicology programs of World War II and beyond. Conversely, the radium studies took their cue from toxicological work with nonradioactive heavy metals conducted in many of the same institutions.

The importance of knowing what fraction of the radon produced from decay of radium in the body was exhaled has been mentioned. This figure is crucial to dosimetry since it determines the amount of energy imparted *in vivo* by all of the daughter chain. A single figure is used, the one associated with long-term retention. Figure 1.1 is a graph reproduced from Silberstein's review (p. 19); it

FIGURE 1.1. Relation of expired radon/total radium to retention time in man. (Redrawn from Silberstein 1945, p. 19. Solid squares represent consolidated data from Aub et al. 1938; and Evans, Harris, and Bunker 1944. Solid circles represent consolidated data from Barker and Schlundt 1930; Schlundt and Failla 1931; Schlundt, Nerancy, and Morris 1933.)

shows that this fraction is far from stable during the first three years. Most of the data shown in figure 1.1 were gathered during the years we have been examining in this section. While details have changed since, I submit this is not bad for what some might regard as "very old" work.

V. Radium Research During World War II

A. Introductory Considerations

It could be conjectured that research with radium would have been greatly reduced, even discontinued, during the years of the Manhattan Project (Manhattan Engineer District, [MED]). After all, there was a large backlog of information on radium, and tremendous efforts were needed on the new problems of the fission products, uranium, and the transuranic elements, the rare earths, and others to be discussed in later chapters. In fact, however, there was considerable additional work with radium. True, it was less emphasized than in the previous two decades, and, in contrast to the feverish activity surrounding the new problems, it was done at a relatively slow pace. The radium work, for example, is hardly mentioned in the monthly reports of the Plutonium Project or other internal documents of the MED.

The logic behind continuation of radium research by the MED lay in the following:

1. Radium-226 was the standard to which many of the new elements had to be compared. Many animal experiments were necessary to learn of the metabolism and toxicity of these new elements. Because of possible species differences, it was deemed advisable to run "control" groups with ^{226}Ra to anchor the new studies to an element we knew something about.
2. The dose-response relationship for radium needed filling-in over a wider range of doses.
3. The effects of fairly high doses needed quantitation because acute exposures to the new elements were considered possible and were being studied in animals.
4. Patients and workers with radium burdens from earlier exposures continued to appear and required both measurement and attention. The continuity of the measurements of body burden and clinical condition could not be broken without threatening most of the previous investment.
5. Many aspects of distribution and retention required more quantitative information.
6. The Armed Services, particularly the U.S. Navy, with requirements for thousands of luminous dials to be painted, wanted to be sure there was no repeat of the exposures during World War I. To this end, they insisted on having an authoritative standard for radium exposure and body burden. We will return to this in chapter 16.

The research with ^{226}Ra in the Manhattan Project was concentrated at two installations, The Metallurgical Laboratory, primarily workers in Chicago, and the project at the University of Rochester Medical School, Rochester, New York. In addition, there was indirect and some nongovernmental support for the continuation of the MIT-MGH work in Boston and Cambridge, Massachusetts, although these laboratories were not officially part of the biomedical effort of

the MED. There was also some anchor-type work done with radium in the University of California, Berkeley, portion of the Metallurgical Laboratory, but this was primarily for range finding.

The wisdom and foresight of Dr. Robert S. Stone, General Medical Director of the Metallurgical Laboratory, must be recognized for providing continuity to the accumulated information on radium and the addition of needed new data.

B. The Chicago Work on Radium-226

Two groups of workers at Chicago can be identified. One, associated primarily with William P. Norris and his colleagues, considered primarily metabolism and toxicity, and under the aegis of Leon Jacobson; hematological effects. The other considered largely longer-term toxicity, particularly carcinogenesis and life-span shortening, and is associated primarily with Miriam Finkel for the experimental work with mice and Austin Brues for some early animal work, later human work, and a general interpretative and philosophical role as a laboratory administrator.^(a)

The work of Norris and Evans (1946) and Jacobson and Simmons (1946) appeared first in Project Reports. Since these papers were never published in their entirety in the open literature,^(b) they will be reviewed in some detail.

The studies by Norris and colleagues involved the toxicity of radium in mice and rats and excretion and retention in mice, rats, and rabbits. The injection route was intraperitoneal or intravenous and the dosages from a little over $2 \mu\text{Ci/g}$ to $0.02 \mu\text{Ci/g}$. The injected radium was metabolized very rapidly. By only two minutes after intravenous injection, less than 10% of the radium could be found in the circulating blood. After intraperitoneal administration, the blood concentration increased rapidly to about 4% of the injected dose, then decreased rapidly. Clearance from the peritoneal cavity was complete within one hour.

There was transient concentration of radium in soft tissues, but only bone retained the element for any extended period. Excretion was rapid, more than 50% of the total occurring within twenty-four hours, with, in the case of the rats, about 60% in feces, 40% in urine. By ten days after administration, excretion attained a very low rate that was maintained thenceforth. Norris found that the early excretion rates could be represented by a linear function plotting $\log E$ (excretion as percent of injected dose per day) against time expressed as $\log T$. The loss function was as the -1.5 power of time for total excretion in the mouse and for urine and feces from the rat, data plotted separately.

Of particular interest is the fact that in all species the retention of radium increased with increasing dose level. This too was related linearly when $\log R$ (percent retention) was plotted against dose level ($\log I$). But the slopes of the lines were different among the three species and even between the two strains of mice (CF1 and what was termed "ABC," although this is not a bona fide strain of mice).

The authors speculated on the possible explanation for this dependence of retention on dosage, and, while attempting to uncover reasons, demonstrated

(a) Some of the very earliest animal work at the Met Lab was initiated by C. Ladd Prosser before either Dr. Finkel or Dr. Brues checked in at Chicago.

(b) These papers were scheduled for inclusion in volumes of the National Nuclear Energy Series (NNEs), which were never published. See Appendix C.

several important basic facts. First was the confirmation of much heavier concentration in the epiphyses of the long bones. Second was differences in deposition in different bones and in teeth, e.g., scapulae and spine were significantly higher than the average, while ulna-radius and teeth were significantly lower. Third, cortical bone metabolizes the radium more slowly than trabecular bone and thus acquires its burden more slowly and holds it more tenaciously. Since there is much more cortical bone than trabecular bone, it is possible that the higher dosage levels might "saturate" the trabecular bone pool and drive relatively more to the cortical bone pool, where it would remain more firmly fixed. Other possibilities could not be ruled out, however.

These were not long-term experiments compared to the durations involved in the work with humans or later postwar work with longer-lived animal species, yet a retention function was desired. Retention after the first ten days appeared to be essentially constant with time. But the range of points was large, and loss as a power function of time shown later in man by Norris, Speckman, and Gustafson (1955) could not be excluded. Indeed, their composite figure (figure 25) indicates the possible validity of the power function for the massed data.

The toxic effects of injected radium at these relatively high doses were gauged by the weight response and survival times. The prime features in the rat are given in the following excerpt from CH-3852 (1946): (a)

1. The earliest effect of radium on weight was seen in a rapid loss. The rate of loss was maximal on the first day and decreased on successive days thereafter.
2. At low injection levels ($0.1 \mu\text{C/g}$ and below), the loss of weight equilibrated almost completely within 30 days, and very little additional relative weight loss occurred until the animals went into their terminal decline.
3. At injection levels of $0.2 \mu\text{C/g}$ and above, the loss of weight was progressive. After the first 20 days, the rate of loss per day became nearly constant. The rate of weight loss increased with amount injected. This is shown quantitatively in table 3, which gives the slopes of the $\alpha(t)$ curves at the various injection levels. The mean rate of loss per day for all intraperitoneally injected groups is plotted against the retained amount of radium in fig. 3. The rate of weight loss is seen to increase in proportion to the amount of radium retained in the body.
4. The initial weight loss was roughly proportional to the amount of radium retained at low injection levels, but increased more slowly at higher injection levels. A measure of the initial loss for each injection level was obtained by determining the average value of Q over the period from 1 to 50 days after injection. This is plotted against retained amount for the 3 lowest injection levels where the initial weight loss was most nearly proportional to the retained radium (fig. 4). The weight loss of rats exposed to daily doses of x rays is also plotted in fig. 4 on the equivalent roentgen scale:

(Norris and Evans 1946)

Effects using survival time criteria are shown here in figure 1.2 for the rat and 1.3 for the mouse.

There appears not to have been a large serial sacrifice experiment done at this time. Thus, pathological observations are limited to those on autopsy at the end

(a) No attempt is made in quotations to translate to current terminology; thus $\mu\text{C} = \mu\text{Ci}$, etc. The numbers given for tables and figures refer to those in CH-3852 and are not reproduced here.

FIGURE 1.2. Influence of the radium content of rats on survival time. Survival is expressed as $(1/M - 1/M_0)$ where M represents the survival time of the treated rat and M_0 the survival time of the normal untreated control. (Redrawn from Norris and Evans 1946.)

FIGURE 1.3. Influence of radium content on the survival time of CF1 female (●) and ABC male (○) mice. Survival is expressed as $(1/M - 1/M_0)$ where M represents the survival time of the treated mouse and M_0 the survival time of the normal untreated control. (Redrawn from Norris and Evans 1946.)

of the terminal phase for each animal and whatever observations could be made on the intact animal during the experiment.

Of special interest among the general pathological findings is calcification of certain soft tissues.^(a) This was most regularly seen in the aorta and resembled arteriosclerosis. It sometimes extended to the large arteries and to the heart. There were also foci of calcification in other soft tissues, usually associated with higher than normal concentrations of radium. This phenomenon was also seen in the Rochester experiments (see section V c). It seems not to occur with any of the other bone-seeking radioelements such as strontium and plutonium, or in fact with any other radioelement. For this reason, the authors considered a possible role of the radon produced from the deposited radium. Naturally no experiment with radium *without* radon could be done to check this postulate. Accompanying this deposition of calcium was a pronounced loss of elasticity of the affected blood vessels so that "the aorta and its branches resembled a system of rigid tubes or pipes" (Norris and Evans 1946).

There was also degeneration and necrosis of muscle fibers of the media of the aorta as seen microscopically.

While the calcification of the aorta occurred quite early in animals (rats) receiving high doses, calcification also occurred in other tissues when the dose was such that the animals lived in excess of one hundred days. There were calcareous lumps in the stomach and a chronic constrictive peritonitis.

The experiments with mice (ABC males and CF1 females) showed approximately the same gross toxicity and gross pathology. In the brown and black animals, there was decided graying of the hair. In the mice, a peculiar condition appeared in one or both eyes in which the eye, on gross examination, appeared to be filled with blood. There was evidence that this caused blindness in the affected eyes. The phenomenon was dose-dependent and occurred in about one-half of the animals living beyond thirty days. It did not appear in the rats.

Other pathology was similar to that seen after moderately high doses of external radiation. However, the calcification process seems to be unique to radium. It is somewhat surprising that this has remained only an observation in the years since this work was done. Both the Chicago and Rochester groups mused a bit on the possible mechanisms involved (and why only radium?), but there was no opportunity for mechanistic experiments then nor has there been clear-cut follow-up in more recent years. It seems likely that these animals had hypertension. Does such an effect extend in lesser degree to low doses and occur in humans as part of the delayed-effects syndrome? Relatively little mention is made of physiological findings in the radium patients and workers, just their anemia and effects in bone. It is not too late to look, however.

Osteogenic sarcoma was notably absent in these studies probably because the high doses terminated life before cancer could develop. One rat in twenty-one that received 15.4 μCi of ^{226}Ra (0.059 $\mu\text{Ci/g}$) developed an osteogenic sarcoma of the right femur, which was noted at 191 days after injection. There were metastases to the lungs. Similarly, one mouse in nineteen developed sarcoma. However, other symptoms of bone damage, such as fractures of the long bones and multiple fractures of the ribs, were common after 100 to 150 days in the rat. (The original report shows roentgenograms of these phenomena, including inability of the fractures to reunite firmly despite adequate callus formation.)

(a) This may be species-dependent.

The second part of this important unpublished series concerns hematological effects (Jacobson and Simmons 1946). Here it was possible to follow the development of effects with serial determinations at each dosage level. Rats, mice, and rabbits were used at dosages of radium chloride comparable to those in the experiment of Norris and Evans (1946), 0.005 to 0.94 $\mu\text{Ci/g}$ in rats, 0.000066 to 0.85 $\mu\text{Ci/g}$ in mice, and 0.0016 to 0.1 $\mu\text{Ci/g}$ in rabbits. Most of the injections were intraperitoneal. Since the results of the few intracardiac injections were very similar, the authors conclude that this difference in route of administration is not significant and report the results without separation by route.

No significant hematologic alterations occurred after an injected amount of 0.01 $\mu\text{Ci/g}$ or less of radium. Doubling the dose to 0.02 $\mu\text{Ci/g}$ produced both anemia and sustained leukopenia in the rats, but a further increase to 0.03 $\mu\text{Ci/g}$ was required to produce severe anemia in the ABC male mice and an initial moderate reduction in leukocytes. These changes were not seen even at this level in the CF1 female mice. The rabbit appeared more resistant still, requiring 0.1 $\mu\text{Ci/g}$ to produce even a moderate reduction in leukocytes and still more to produce anemia. Higher doses reduced reticulocytes and platelets. At the lower doses, the peripheral blood changes showed recovery until the terminal stages, but recovery was moderate or absent at the higher doses.

Follow-up on the possible validity of the species and strain differences seen does not seem to have been possible in this pioneering experiment.^(a)

There were morphological changes such as increase in red cell diameter and mean corpuscular hemoglobin, i.e., macrocytic anemia at doses in the 0.1- to 0.2- $\mu\text{Ci/g}$ range. These changes were similar to those seen after administration of either external x- or gamma radiation.

The other large experiment at Chicago involving ^{226}Ra was of much later origin. It began the now classic comparison of carcinogenic potency of several bone seekers relative to radium reported from Argonne National Laboratory in the postwar years. Since this is pertinent largely to comparative toxicity, discussion will be reserved for the chapters comparing radium with the fission products and the actinides. The fact that it was apparently begun under MED auspices should be recognized here, however.

A series of mice and rats given radium by intraperitoneal injection are listed in the appendix to Bloom's classic treatise on the histopathology of irradiation (Bloom 1948). The effects are taken up in conjunction with each major organ system and compared with beta-ray sources and x rays. The peculiar vascular changes are mentioned again along with the fact that the peculiar calcium-like deposits are highly radioactive. The Bloom book is a major compendium of the histopathology studies done by the Metallurgical Laboratory and should be consulted for both a broad overview and specifics for any radionuclides.

C. Experiments at Rochester with Radium-226

The work at the Rochester Project was done as part of a general investigation of the biological effects of alpha emitters. It was published in detail in the volume

(a) This experiment was paired with a comparable one using plutonium, and the report gives data on comparative effectiveness of plutonium and radium. This seems to be the first such comparison reported. It will be discussed in chapter 7.

edited by Robert Fink in the National Nuclear Energy Series (Fink 1950).^(a) As in many other instances, the work with ^{226}Ra was done primarily to establish "control" or bench-mark data for the effects of lesser-studied elements under the same experimental conditions in the same animal species. But they contributed also to our understanding of the effects of radium itself.

The volume (Fink 1950) contains a very useful historical background chapter by H. E. Silberstein (Silberstein 1950a), distribution and excretion studies with rats (Silberstein 1950b), and the results of two large experiments on the intravenous lethal dosage of polonium, plutonium, and radium in rats (Boyd et al. 1950 a,b).

The Rochester workers stuck fairly assiduously to the intravenous route of administration^(b) as "the only quantitative method of ascertaining how much radium is in the body as a whole and actually available for excretion or deposition in the tissues at any time" (Silberstein 1950b, p. 179). Besides acting as anchor points for the comparisons, the experiments were designed to help establish excretion rates for use in bioassay and the measurement of long-term retention.

Since the Rochester results are fully available in the open literature, they will be dealt with somewhat more briefly than the unpublished Chicago work. It is amply clear that the two groups worked quite independently, although they probably had interchange of results after the lifting of security measures at the end of the war. The doses, expressed as microcuries per kilogram, were in the same range as those already reported for the Chicago work. Each rat is reported individually like a clinical case report so that the reader can see what happened in each individual. Yet composite graphs are drawn to show general trends. This applies to daily excretion figures and the tissue contents in animals sacrificed serially from 1 day to 300 days. There are tables for tissue contents at 24 hours, 10 days, 50 days, 236 days, and 300 days.

The work on distribution and excretion in the rat can be summarized by pointing out the contrasts to man elucidated by the authors:

1. The rat excretes radium much more efficiently than does man.
2. The rat releases approximately equal quantities in urine and feces, whereas in the human only one-tenth of the total excretion is via the urine.
3. These apparent differences in excretion of radium do not explain fully the differences between rat and man.

There is no doubt from both these experiments and those at Chicago that radium leaves the bloodstream much more rapidly than kidney excretion alone can account for. There is no reason to believe this is not also true in man. The excretion kinetics as plotted in the composite curves show an extremely rapid decline in urinary excretion rate in the first twenty-four hours—over a factor of one hundred—and almost as rapid a decline in fecal excretion rate with time. The percentage of dose retained continues to fall off slowly over the period from a few days to three hundred days, somewhat in contrast to some earlier work that indicated almost no loss once the period of rapid excretion had ceased.

The Rochester workers made no point of retention being a power function of dose, as described by Norris and Evans (1946), nor do their data indicate it. The

(a) Although published postwar, all volumes in the NNES refer to work done during the MED days except for data collation, editing, etc.

(b) There were two experiments using oral administration.

range of doses is not quite as great as in the Chicago work, but sufficient to show an effect the size of that described by Norris and Evans. No explanation is apparent for this difference. Indeed, the contrast was not really known to exist until it was too late to check for explanations by further experiments.

Two rats were given radium orally in a single dose. The figures show considerable spread between the two animals, but confirm that radium is moderately well absorbed from the gut and that excretion continues at its higher level for somewhat longer than after intravenous administration. This phenomenon is seen with other elements and may be taken to reflect the fact that orally administered materials show less tendency to form radiocolloids in the blood and tissues.

The biomedical effects of injected radium chloride were investigated in two extensive experiments. Polonium and plutonium were involved also. These two experiments, reported by Boyd et al. in chapters 7 and 8 of the Fink volume (Fink 1950), included extensive general and some special pathology and hematological observations.

Weight response and survival time were used as quantitative measures of the lethal effects. A large staff of pathologists, hematologists, and a statistician took part in both experiments. In the first experiment, termed "pilot studies," from two to six rats per dosage level were involved, and dosages from 17 to 8,000 $\mu\text{Ci/kg}$ were given. The second experiment, termed "intravenous lethal dosage," involved approximately ninety rats receiving radium (out of five hundred in the total experiment) at doses from 240 to 6,430 $\mu\text{Ci/kg}$ of ^{226}Ra . There is extensive and well-organized documentation for all findings, including separate sections on the hematology. The principal results can be summarized as follows:

1. Despite the large difference in size between the two experiments, the results are roughly comparable. The second experiment, however, was large enough to establish statistical validity for LD_{50} calculations.
2. The LD_{50} for radium was 2,100 $\mu\text{Ci/kg}$ at twenty days, 735 $\mu\text{Ci/kg}$ at sixty days, and 320 $\mu\text{Ci/kg}$ at one hundred days. These indicate that radium is not a highly effective toxic agent in producing acute lethality. Many other elements are considerably more effective in producing acute lethal effects. (See later chapters.) A possible chemical effect may account for the sudden death during or close to injection of one or two animals receiving very high doses.
3. The pathological effects were in general comparable to those seen with acute doses in the range of 500 roentgens of whole-body x-irradiation. These effects included marked changes in lung, liver, and gastrointestinal tract; depletion with some regeneration of germinal elements of the testes; only a small depletion of functional elements in the ovaries; marked decrease of functional cells in all of the hematopoietic organs, with frank atrophy at higher doses.
4. The unique calcification of the large blood vessels described in the Chicago radium experiments was found in the Rochester work, along with calcification of the trachea.
5. Bone changes were largely seen as depletion of osteoblasts and osteoclasts in almost all animals and degeneration in the epiphyses of about a third of the animals receiving radium. Five sarcomas were seen in the pilot experiment—one an osteogenic sarcoma—but there were too few animals to establish this as being caused by the radium.

6. The hematological changes can be summarized by table 1.1, taken from the publication. These results were from the pilot experiment. The fall in leukocyte count appeared to be linear on a plot of log radium dosage against lowest leukocyte count in percent of original or control.
7. Retention was measured in some of the animals. When mean activity remaining is plotted on a logarithmic scale versus mean survival time on a linear scale, a two-phase relationship is seen: a rapid phase lasting up to about fifteen days, and a slower phase out to eighty days, both linear on the semilog plot. It is not possible to determine that this is really different from the power function relationship described in the Chicago work, partly because of the relatively short time-span involved.
8. Weight loss is continuous from injection to death, its rate being dependent on dosage.

TABLE 1.1. Summary of the Effect of Injection of Radium Chloride on the Peripheral Blood Count of Rats*

Blood Constituent	Remarks
Erythrocytes	300 microcuries per kilogram and above resulted in anemia provided animals survived
Hemoglobin	300 microcuries per kilogram and above resulted in anemia provided animals survived
% Reticulocytes	700 microcuries per kilogram and above, a fall; minimum level at 7 days followed by a rise; most rats from 17 to 1,000 microcuries per kilogram showed spiking elevation between 15 and 50 days
Platelets	Early slight suppression between 17 and 300 microcuries per kilogram; above 300 microcuries per kilogram, definite suppression
Leucocytes	Immediate fall from 17 through 175 and 700 microcuries per kilogram with terminal rise in leucocyte count; a greater fall in doses above this, reaching zero 24 days after injection of 4,000 microcuries per kilogram
Absolute neutrophils	Early fall after 17 microcuries per kilogram and above; up to 900 microcuries per kilogram initial fall followed by rise until animal's death; doses above showed less tendency toward terminal rises
Absolute lymphocytes	Definite fall after 51 microcuries per kilogram which increases with higher dosage; 22 days after injection of 4,000 microcuries per kilogram fall to almost zero.

*Comparison made with controls and initial counts.

Source: Reset from Boyd et al. 1950a, chapter 7, p. 285 in Fink 1950.

The information on relative toxicity of polonium, plutonium, and radium gathered in these experiments will be taken up in chapter 7.

One extremely useful feature of both the design of the Rochester experiments and the method of reporting the results is the closeness one feels to the original data. Unlike much reporting in more recent years, forced upon us by the pressures of publication space and cost, it is possible to follow either individual animals or individual entities of relatively small scope in each experiment. Thus, the work contributes a feeling of security about tracing each conclusion,

each statement of fact, to the original data or closely related summaries. The monograph also gives very complete details on methodology for handling the injection solutions, animal care, assay of tissue and excreta and so forth.

D. Radium Research at Massachusetts Institute of Technology-Harvard-Massachusetts General Hospital During World War II

The Massachusetts Institute of Technology-Massachusetts General Hospital (MIT-MGH) program was already well established with financial support from philanthropic foundations and other sources when the Manhattan Engineer District was organized. It did not become officially a part of the MED effort. In fact, its personnel were involved in a variety of war research activities along other lines, and the radium work was not front and center to the degree it had been. Nevertheless, the task of measuring radium body burdens in patients, dial painters, and other workers continued, in part, by taking the Sundays not devoted to war work. Some things that could not be done at the time were put aside for postwar studies. Mary Margaret Shanahan, Dr. Evans's invaluable administrative and research assistant, kept doggedly at the task of compiling the rosters of individuals who did, or might, have significant body burdens, and of following up those who had been in for measurement. A group of dial painters from the Waterbury Clock Company, Waterbury, Connecticut, was added to the file, among others, for checkup and follow-up. Since the results of these studies fit easily with reports of later postwar years, details will be reserved for the section describing those years.

Between 1936 and 1941, the MIT group engaged in one of its few forays into work with animals. There were four series of experiments involving Wistar rats that were fed radium from medicine droppers or given intradermal injections (one series). Since the results were not reported until 1944, in two papers, they fall into the time-span of this section. The first paper, by Evans, Harris, and Bunker (1944), considered both metabolism and effects. The second paper, by Dunlap et al. (1944), concerned largely effects, especially the development of transplantable osteogenic sarcomas by feeding radium. The doses were moderately large in the aggregate (50 to 100 μ g fed) and were given as daily or every-other-day feedings, for a period that varied from ten to twenty days. Actual doses were calculated by first measuring the gamma-ray activity of the unopened ampule and subtracting from it the activity remaining in droppers, bottles, glove washings, and empty ampules. The sources of the radium were different and contained varying ratios of barium to radium, but the authors evidently found no difference in results attributable to this factor. Radium contents of tissues and residuum were measured using both the radon and the gamma-ray detection methods. As is characteristic of most work with radium salts handled in glass, there was a fairly large spread in actual dosages compared to the intended dosage. However, the authors report data for each animal individually so that this factor does not complicate the reporting.

The results can be summarized as follows:

1. The metabolism results, like those already discussed, showed very rapid initial excretion. Average retention at the time of death was about 2.2% of the amount fed. Excretion rate after the initial rapid phase ranged from 0.14% to 0.6% of the body content per day.
2. The rat exhales a much higher fraction of the radon produced from radium decay than does man. Radon exhalation averaged 85% of the body radium

- exhibited during life. The remaining 15% showed as gamma-ray emission. There was less exhaled as radon after intradermal injection (60% to 75%).
- 3. The skeleton contained most of the radium. The other organs contained less than 1% as much radium per gram.
- 4. Of the soft tissues, lung generally had the highest and heart the lowest concentrations.
- 5. Osteogenic sarcoma was found in each set of experiments and was transplantable.^(a) The lesions reproduced with fair fidelity the osteogenic sarcomas seen in the human radium cases, as did other aspects of the pathology.
- 6. An outstanding difference between rat and man was the finding of hypoplastic bone marrow in the rats. In contrast, the dial painters had a hyperplastic, regenerative marrow.
- 7. Perhaps the most critical difference was in the apparent sensitivities of rat and man to radium. The rat requires, according to these experiments, from 150 to 200 times as much radium in the skeleton to produce chronic symptoms comparable to those seen in man. On the basis of skeletal ratio of radium to calcium, the factor is at least 250. These facts so impressed Robley Evans that he vowed never to indulge in another experiment with animals intended to provide information needed for direct application to man. And to nail down the contention that the rat is unsuitable for any quantitative applications to man, the authors appended a table showing ratios between rat and man for the maintenance dose of certain vitamins and essential minerals, and for the toxic dose of eight metals. In every case, the rat was found to be less sensitive by ratios of from 1.9 to 152.0. Dr. Evans has participated throughout his career in joint endeavors among physicists, biologists, physicians, and others, and continues to do so. He has acted as advisor to later important animal experiments. But in terms of his personal research, he seems to have maintained his resolve to eschew animal experiments, maintaining with Pope that "The proper study of man is man" (Evans 1978a,b).

E. Other Studies

Obviously, there were other investigations of radium in man and animals during these years, but they fall in general outside of the scope of this work. Mention should be made of a few, however.

- 1. Dr. Frank Hoecker with the U.S. Public Health Service during part of the period of our interest, and later at the University of Kansas, published in the *Journal of Industrial Hygiene and Toxicology* on the use of the Rn/CO_2 ratio in breath as an index of excessive radium absorption, and on the coefficient of elimination of radium (Hoecker 1944a,b). Hoecker continued in the field for many years as sort of an independent, not directly associated with any of the major groups.
- 2. The MED supported work on carcinogenesis in the laboratory of Egon Lorenz at the National Cancer Institute. Most of this concerned external

(a) It should be noted that a Dr. Austin M. Brues is acknowledged as having explanted and grown fragments of two tumors in tissue culture. This was during his early years with the Harvard group and before he became involved with the MED at the Met Lab and later the AEC, as Director of the Biology Division of Argonne National Laboratory.

radiation and radon, but there was some work on radium metabolism in the mouse. This was issued as a declassified report from the Argonne National Laboratory, which was the contractor for Lorenz's project at the time of publication. (See Weikel and Lorenz 1947.)

3. A series of papers appeared in translations of USSR work indicating increased yields of crop plants in the presence of radium and other radioactive elements. Shades of the polemic of the previous decade in human medicine! They also reported the uptake and metabolism of various elements by plants. Since these papers were seen only as abstracts, no judgment can be made on the validity of the particular conclusions drawn. But the idea of stimulation of plant growth by radium was popular in the United States throughout the 1920s and 1930s (see Badash 1979). Indeed, the apparent stimulation of many life processes at low levels of assault by injurious agents may be a ubiquitous phenomenon. Whether the "stimulation" is for the ultimate good of the organism involved or not is problematical. It may still be of benefit to a party interested in crop yields, for example, but is likely to be injurious in the long run to the organism "stimulated" (see Dubkov 1940, 1941).

VI. Postwar Radium Research

A. General Comments

The uncertainty that clouded the future of many of the wartime research efforts when World War II drew to a close naturally included the plans for continuation, expansion, or contraction of research with radium. But two important differences from the general atmosphere greatly reduced its impact. First, the scientists involved were, in general, doing something closely akin to their permanent interests. There was not the mass exodus to return to environments and fields of research interrupted by the call to war work.

The MIT-MGH group was ready and more than willing to bring the radium studies from the back to the front burner. The Chicago group, although decimated in other areas, had the good fortune to have most of those concerned with the radium studies remain happily on the job. At Rochester, many of those who were closest to the radium work migrated to California. But those with long-held interests, e.g., William F. Bale, remained, and new, postwar staff continued the general program with internal emitters, including ^{226}Ra .

The second difference was financial support. The newly organized Office of Naval Research (ONR) stepped into the gap between the termination of support from the wartime agencies and the beginning of direct support from the U.S. Atomic Energy Commission (AEC) with most timely and far-sighted financial help. This included the work on radium at MIT.

The decades from 1947 until the late 1970s, the theoretical cutoff point for this chapter, turned out to be the best era yet for research with radium. The human cases named for follow-up went from a few hundred to at least twenty-five hundred (Brues 1976) individual files. Indeed, the total register may now have reached five thousand names (Rowland, Stehney, and Lucas 1977) if all of those suspected of having been exposed to radium, and potentially traceable, are included. The number for whom measurements of radium contents exist approximates sixteen hundred. Vigorous efforts are continuing to locate and

study as many as possible of those remaining. The information gathered has been standardized and computerized. Sufficient data are now available to describe retention functions with considerable confidence.

Along with the studies on man, radium was introduced into the long-term animal experiments started after the war. This has added the virtues of controlled experimentation where the doses are well known. Also, many of the questions of relating data gathered from animal experiments to the situation in man can be attacked with significant data on both sides of the equation.

In the postwar atmosphere, much more attention could be paid to basic mechanisms. It would not be an exaggeration to say that a large portion of the new knowledge about the dynamics of minerals in bone and the probable mechanisms of effects is tied to the work with radium and other bone-seeking radionuclides.

Also, new populations were discovered. These included a set of dial painters in Ottawa and La Salle-Peru, Illinois; and in Pittsburgh, Pennsylvania; and an entirely different set of exposed people in Germany. The latter involved the shorter-half-life (3.6 days) isotope of radium, ^{224}Ra , the study of which, while far from complete, has already added materially to the broad picture of radium toxicology.

These developments will be taken up in whatever detail is relevant to the purposes at hand in the sections below, starting first with the oldest and longest continuous study, the MIT-MGH work.

B. Postwar Radium Research at the Massachusetts Institute of Technology

Dr. Robley D. Evans had the pleasure one Saturday morning around V-J day of a visit from a Dr. Robert Conrad of the newly formed ONR. Conrad stated, "We have selected some laboratories over the country which we regard as national assets. The Admiral^(a) says yours is one of them. How much money do you want?" Evans, always the pragmatist, asked what they were supposed to do. After all, the military had been requesting specific jobs ever since 1941. The response implied that there were no strings. Just keep on doing the radium work they had been doing.

Thus began one facet of a saga too little recognized in the history of scientific research in the immediate postwar years. While the struggle over civilian versus military control of atomic energy raged and was finally resolved by organization of the AEC, the ONR stepped in to keep important groups together and to keep continuity in important projects. This was done first by direct use of Navy funds and later by use of funds appropriated for the AEC but distributed and administered by ONR while the AEC was getting organized.

As soon as the AEC was organized and had a director for the Division of Biology and Medicine—Dr. Shields Warren from Harvard-New England Deaconess Hospital—Evans was encouraged to bring the radium work, especially the crucial follow-up of the dial painters, chemists, and other radium workers and patients with the iatrogenic body burdens, into full bloom. From that point forward, the MIT-MGH work, which had depended largely on

(a) "The Admiral" was probably Rear Adm. H. J. Bowen, former head of the Navy's Special Devices Center who had much to do with the launching of the Office of Naval Research.

nongovernmental sources of support, was an official activity of the United States government through contracts. It still is, although differently organized.

Space does not permit a detailed review of what was done, nor is it needed since the annual reports and numerous summaries at symposia provide easy and in-depth documentation. Some of the highlights will appear in this section.

1. Growth of the Populations

The numerical growth of the total population at all laboratories has already been summarized. The MIT group, up to the time of consolidation of their studies with those at Argonne National Laboratory, had studied about 800 individuals, some 600 or so living, about 60 by autopsies of exhumation cases, and 120 unexposed matched living controls (Evans, Keane, and Shanahan 1972). The process of follow-up on the dial painters from the Waterbury Clock Company and New England Watch Company, begun during the war, was expanded. The New Jersey dial painters, studied for a while in an independent project, were eventually folded in to a considerable extent. A new population of dial painters was added from the Standard Chemical Company in Pittsburgh.^(a) The circumstances of this find are described in the following excerpt from the May 1961 Annual Progress Report of the MIT Laboratory (MIT 1961):

For the first time there have been a number of patients from the Pittsburgh area. When the Flannery Building was being renovated for a new tenant, it was found that a very extensive decontamination job had to be done to eliminate the radioactive material which remained from the period when the Standard Chemical Company occupied the 4th and 5th floors. This contamination received a great deal of publicity in the Pittsburgh area and this in turn prompted former workers of the Standard Chemical Company to get in touch with the State Department of Health. Every attempt was made to reassure these people that there was very little likelihood of their having suffered any damage. Workers from the State Department of Health interviewed a large number of these people and collected breath samples in flasks from a number of them. Former dial painters and chemists were encouraged to be tested for residual radioactivity either at MIT or at Argonne National Laboratory. Nineteen individuals came to MIT where a complete battery of tests, both medical and physical, were carried out (see Tables 5 and 6).
(MIT 1961, p. 13)

Each annual progress report gives details not only of the source of the individuals studied in the several populations, but protocols of the data obtained from those studied during that particular year. The population was broadened to include a large variety of sources, even some cases bearing a body burden from thorium-series isotopes gained by the administration of Thorotrast (see chapter 4).

2. What Is a Suitable Population?

The reports from the MIT group emphasize the possibilities of bias brought into the populations studied. (These problems were, of course, general to the field and were recognized by most workers to a varying degree and with varying ideas for solution.) The early population was made up almost entirely of individuals who either sought aid because they had symptoms or were referred by physicians who suspected their problems might have been caused by deposited

(a) Some of these were also studied at the Argonne National Laboratory in the late 1950s and the 1960s.

radium. These are frequently described as "walk-ins." Their counterparts without problems would be unlikely to enter the study. The "walk-ins" were designated by the MIT workers as in general "*epidemiologically unsuitable*" for purposes of establishing dose-response relationships.

Throughout the postwar decades at MIT, much of the effort was to bring in all possible exposed persons for measurement and thus broaden the base of epidemiologically suitable subjects. This follow-up included bringing numerous persons to MIT for measurement or securing breath samples for radon measurement plus whatever medical information could be obtained in situ from those who could not or would not come to be measured. It also included much work in arranging for exhumations as well as the estimation of body burden through measurement of samples of bone obtained from deceased individuals at autopsy.

These efforts have undoubtedly reduced the bias in the effects data. Evans has been very careful to use only what he regards as the epidemiologically suitable cases for any quantitative determination of dose-effect relationships (Evans, Keane, and Shanahan 1972). There are those who feel that any overrepresentation in the registry of cases with symptoms may be balanced by underrepresentation of early cases with high burdens who died before the studies began, as well as those with low burdens who died from other causes before they could be included in the registry. Nevertheless, from the standpoint of pure epidemiology, the study is still open-ended since a surprisingly large number in the registry are alive today. In fact, many are expected to live well into the twenty-first century. The books cannot be closed nor the study curtailed until after this final stage. This is true even though satisfactory statistical validity was attained by the mid-1960s.

3. Expression of Dose

In the earlier MIT measurements, the radium burden was expressed in microcuries, or micrograms. As knowledge expanded concerning the biological effects from x or gamma or other external radiation sources, it was tempting to translate microcuries into absorbed dose in rad for comparative purposes. The MIT studies gradually shifted from simple microcuries to "pure radium equivalent" (see next section) and to "cumulative rad." As Evans, Keane, and Shanahan (1972) explained, many of the biologically relevant dosage parameters such as measured residual body burden, extrapolated initial burden, and maximum dose rate do not convey information concerning the protraction of the radiation insult. A unit involving some integral of rate and duration of the irradiation was desired. What was utilized, for convenience only and not to be interpreted as representing the dose to individual target tissues, was the gravimetric average skeletal absorbed dose expressed as cumulative rad or "CR." The nuances of this choice are detailed in Evans's Sylvanus Thompson Lecture (Evans 1966). Most recent summaries from the MIT group utilize this mode of expressing dose from radium. It can be regarded as a forerunner of committed dose equivalent and related entities of more recent origin.

4. The Role of Mesothorium—The MsTh/Ra Ratio

The dial-paint mixture used in the early days was not of constant composition either among different plants or at different times in a given plant. The chief variable was the presence or absence and amount of ^{228}Ra (classically called

"mesothorium," MsTh). It has a much shorter half-life than ^{226}Ra , about 5.7 yr^(a) versus 1,600 yr for ^{226}Ra . It will be remembered that the early paints had so much MsTh that Martland described the early cases as "mesothorium poisoning." Because of the shorter half-life, the MsTh delivers its radiation dose, and that from its daughters, much sooner than ^{226}Ra on an equal microcurie basis. Thus, depending upon the amount of MsTh in the compound, the actual radiation dose may be many times greater at early times than that inferred from the residual ^{226}Ra measured many years after exposure.^(b)

Proper estimation of radiation dose to the dial painters requires good determination of the presence or absence of mesothorium and its decay products and the ratio of MsTh to ^{226}Ra at the time of measurement, a difficult and uncertain task. The MIT group did their best, including diligent attempts to get samples of the paint used, which would provide activity levels in the range of the instrumentation available.^(c) If that failed, in-vivo measurements of thoron exhalation were made. The very short half-life of thoron (54 sec) made that a difficult task because:

not much was left for exhalation;

transfer from the site of release to the lungs is far from complete and is quite variable;

the gas decays so quickly after collection that the actual measurements were frequently of the thorium B and C decay products, which plated out electrostatically on the surfaces of the collection devices.

The annual reports of the 1950s give us a clear picture of the frustrations of such measurements, even in a laboratory devoted primarily to applied physics.

The advent of the sodium iodide crystal counter and, later, installation of a whole-body counting facility at MIT (which they called "controlled background facility" or "CBF") changed all of that (MIT 1959). The 2.62-MeV gamma ray from ThC, one of the daughter products of mesothorium, could be measured with relative ease so long as appreciable quantities of MsTh had been present originally.

On the basis of these and earlier measurements, it could be concluded that, in about half of the MIT cases, from 50% to 90% of the total alpha-radiation dose came from the MsTh chain. In the rest, it was much smaller.

- (a) The half-life was thought to be about 6.7 yr until C.W. Mays (Utah) recognized an ambiguity in the decay data. The more reliable value was pointed out in the 1960 annual report from MIT (MIT 1961, p. 1415).
- (b) Radiothorium (RaTh), the second product in the MsTh decay series and an alpha emitter, is actually of much more importance than MsTh itself, which is a beta-particle emitter. A detailed exposition of these relationships is given by Aub et al. (1952).
- (c) The variable use of mesothorium in self-luminous compounds by one company, the United States Radium Corporation, is shown vividly in table 1 of Aub et al. 1952. In the period 1917 to 1923, the MsTh/Ra ratio, expressed after three years of aging, was 0.92; in 1926 it was 0.32; in 1927 it was 0.23. Some confusion has been introduced into the literature by attempts to lump together luminizers from one company as "high mesothorium" and others as "low mesothorium." This requires great care in ascertaining the time frame. Also the nostrum "Radithor" showed great variability with time. Thus, the safest path is to know the individual MsTh/Ra ratio. Only the Ottawa, Illinois luminizers and the radium patients who received intravenous injections can be reliably thought to have received pure radium.

A striking illustration of the relative contribution that mesothorium can make to the total alpha dose is seen in figure 1.4, taken from Aub et al. (1952).

FIGURE 1.4. Illustration of the importance of the dose from mesothorium especially in the early years. The lower curve shows the alpha-ray tissue dose from ^{226}Ra , assuming it was ingested in 1920. The excretion rate has a half-period of forty-five years, and the ^{226}Ra dose is taken as unity in 1950. The upper curve shows the total alpha-ray dose from a mixture of MsTh and radium in a paint of average composition in the period 1917 to 1923. (Redrawn from Aub et al. 1952, p. 323. Reprinted with permission of The Williams & Wilkins Co., Baltimore, copyright 1952.)

5. The Pure Radium Equivalent

Even before the advances in instrumentation made measurement of mesothorium an easier task, the need was felt for a single unit that could express the radiation delivered to the skeleton in cases with quite different fractions of the dose from MsTh versus ^{226}Ra . The MIT group developed an expression for this known as the Pure Radium Equivalent or PRE, defined as:

$$\text{PRE} = \left[1 + \left(\frac{\text{present MsTh/Ra ratio}}{\text{ratio}} \right) \times \left(\frac{\text{MsTh decay since first exposure}}{\text{decay since first exposure}} \right) \times \left(\frac{\text{ratio in rad/}\mu\text{Ci}}{\text{MsTh/Ra}} \right) \right] \times \mu\text{Ci-}^{226}\text{Ra}.$$

If it is assumed that the present MsTh/Ra ratio can be measured, and the time of initial exposure is determinable, the rest follows by using a physical half-life of 5.7 yr for MsTh and adjusting the ratio of rad/ μ Ci for MsTh compared to radium according to the time since deposition, the relative energies imparted by the thorium and radium decay chains, and the respective fractions lost in the gaseous daughters (Evans 1967). In typical cases, the PRE may be boosted to as much as ten times the dose associated with a comparable amount of ^{226}Ra alone. Let it be emphasized, however, that the end result is still in rad. As we shall see in a subsequent section, there is reason to believe that rad from ^{228}Ra are more effective by a factor of two to three than rad from ^{226}Ra .

It must have been during this period that Dr. Louis Hempelmann nearly froze. Hempelmann, a physician-radiologist now at the University of Rochester Medical School, was in the early 1950s part of the medical team at Harvard-Massachusetts General Hospital, which did the clinical work-ups on the MIT patients. Evans and Hempelmann had been musing on the many unexplained differences among the dial painters and Radithor drinkers compared to the radium patients and chemists. The possible contributions of MsTh were, of course, much on their minds, but they had not been able to be quantitative. Indeed the data were very unsatisfactory. By the time of this incident, Hempelmann had moved to Rochester but was still much involved with the radium work. He was at home one cold day enjoying a hot postexercise shower (Hempelmann is an avid squash player) when he received a message that Dr. Evans wanted him on the telephone. Wrapping a towel about his middle, he proceeded to the phone to find Evans ecstatic over the way the now measurable mesothorium content explained many of the differences. The enthusiasm lasted for one and a half hours and might have gone on longer except for the noise of Hempelmann's teeth chattering!

6. The Biological Effects

A landmark paper describing the effects of deposited radium in man is the one already cited in another connection by Aub et al. (1952). While it takes up only thirty patients, a small fraction of the total by the late 1960s, the analysis is so thorough and detailed that subsequent work needed only to relate to one or another of the examples given in this paper. There is a complete clinical description of each case along with a review of the pertinent biological and physical properties of radium and mesothorium.

The sophistication of the biomedical studies of the radium cases had grown apace with the improved physical measurements. By the 1960s, a battery of fifty-six biomedical parameters for measurement was developed (Maletskos et al. 1964; Evans 1967). The easiest among these was, of course, the development of frank malignancies. But skeletal changes of more subtle nature were important too. To quantify these, a system was worked out by Dr. Gary in collaboration with Drs. Robert J. Hasterlik and Asher J. Finkel of the Argonne group based upon the examination of roentgenograms. A sample of the scoring sheet is given by Evans (1967) and in other reports from MIT. The scoring system was tested repeatedly by all concerned until they were satisfied that there were few, if any, differences in interpretation of the radiographs (Hasterlik 1980). This scoring system, called the x-ray score, became one of the most satisfactory measures of overall effects of the radium and daughter products on bone. Many of the MIT results are presented as x-ray score versus PRE.

After some further use, it was deemed desirable to show results in two ways, with or without the sarcoma incidence included. (Sarcomas rated a five, the highest score in the system, and tended to overload the picture for scoring other changes.) The score with sarcomas included became known as the "classical x-ray score," that without the sarcomas as the "reduced-x-ray score." In the later reports, one or the other of these was plotted against cumulative rad (CR) in presenting the results.

A plot of classical x-ray score versus dose in cumulative rad for the MIT cases studied through 1969 is reproduced as figure 1.5. Tumor incidence in the same MIT cases is shown in figure 1.6.

In both instances, there appears to be no effect below somewhere around 500 CR on the basis of the classical x-ray score or below about 1,000 CR on the basis of cumulative tumor incidence. It appears that the classical x-ray score continues to rise with dose, but the tumor incidence levels off at about 30%, except for the very highest CR doses, where it may be higher but not outside the range of mean occurrence.

This relation has held up through many testings and much manipulation of and additions to the data. Since tumor incidence times increase with decreasing doses (see figure 3 of Evans, Keane, and Shanahan 1972), it can be argued that the latent period for tumor formation becomes longer than the life span of the individual at about 1,000 CR. The relationship was taken by the MIT-MGH group as indicating there is a domain at low doses that can be designated as a *practical threshold*. The failure of tumor incidence to increase beyond about 30% can be interpreted as saying that only about 30% of human beings can develop bone sarcoma no matter what the dose from radium.

A considerable polemic has grown up around these relationships, and dose-response curves have been derived from other sources and with other elements, as we will see. For our present purposes, it is enough to present these relationships as summary findings from the MIT work derived from a set of internally consistent and exhaustively analyzed results.

It will be noted in figure 1.5 that the tumors include carcinomas of the sinus or mastoid in addition to bone sarcomas. The carcinomas are thought by some to be due to radon released from radium decay that can enter these air chambers and bombard the mucous membrane lining as well as deposit decay products on the surfaces. This could, of course, be an effect associated uniquely with radium deposits and not mesothorium or other bone seekers that do not release appreciable quantities of alpha-active gas. However, mastoid and paranasal air cells have epithelium closely applied to bone that may be bombarded directly by alpha particles emanating from bone surfaces. Thus, the effect cannot be tied solely to radon emanation. In recent years, cancer of these areas has been found in many other inhalation exposure situations. The story is still unfolding.

As Stannard stated (1973), the 1972 paper by Evans and colleagues constitutes a sort of valedictory on the forty-plus years of work of the MIT Radioactivity Center. It reflects not only the careful analysis of accumulated work but bespeaks the wisdom of the Office of Naval Research and later the Division of Biology and Medicine of AEC in keeping the Laboratory and the group intact and prospering.

After a discussion of radium studies at Argonne, we shall examine the work of the Center for Human Radiobiology, which was formed by a consolidation of the MIT and Argonne cases toward the end of the period we have been examining.

C. Postwar Radium Research at Chicago (Argonne National Laboratory/Argonne Cancer Research Hospital)

1. General Comments

At the end of World War II, the Metallurgical Project gradually dissolved along with the Manhattan Engineer District. The Chicago portion became the Argonne National Laboratory (ANL) with new buildings and equipment built outside of Chicago near Lemont, Illinois, and hard by the site of the old Argonne reactor. Biology and Health Physics Divisions were organized, the animal facilities were greatly improved, and a major interrelationship with the University of Chicago Medical School developed. A bit later, potential for clinical input was increased by the organization of the Argonne Cancer Research Hospital (ACRH). There was a loose connection between this new organization and the Argonne National Laboratory, which was most fully expressed in the radium studies.

The Division of Biological and Medical Research of ANL was directed by Dr. Austin M. Brues, whose contact with radium work we have already noted. John Rose, a well-known radiological physicist headed the Health Physics (soon renamed Radiological Physics) Division, and he worked in close association with Leo Marinelli, who was associate director for research. Both of these men, especially Marinelli, and their associates had strong interests in internal emitter toxicology.

The Laboratory became and has been a leader in all fields of postwar atomic energy research. The biomedical program, although somewhat modified in general emphasis, maintained the work with radium already under way and added major new work. Because of the association with the ACRH and the presence of physicians such as Drs. A. Finkel and R. Hasterlik in the program, much more work on human patients and workers could be added.

2. Retention of Radium

In section V, we reviewed early work done primarily by William P. Norris and associates on the metabolism, i.e., transfer functions, of ^{226}Ra . Most of the studies reported then were from animal populations. After the war, these were extended into long-term studies on man, primarily, but not exclusively, the patients at the Elgin State Hospital where Schlundt had measured body contents in the 1930s. Norris's work was actually begun during the MED days but had to extend into the postwar years to allow for evaluation of long-term kinetics of retention and excretion.

Earlier in-house reports and general conclusions were well summarized in two papers published by Norris, Speckman, and Gustafson in 1955 and by Norris, Tyler, and Brues in 1958.

The results confirmed much of the earlier work on the metabolism of radium and extended its range and sophistication. Perhaps of most import for future work was the mounting evidence that the power function relationship seen in the animal work was even more clearly descriptive of retention of ^{226}Ra in man. It took a special effort to make this conclusion stick. Most radioisotopes leave the body by first-order kinetics (i.e., as an exponential function of time). The power function had no obvious basis in physiology and has its difficulties of application to very short times. But the data kept giving straight lines when plotted as log retention against log time. The power function was gradually accepted as probably the best description and was used for calculating radium

burdens extrapolated to times prior to or after the time of a measurement. It became known as the "Norris function."

After a single intravenous injection, the relation took the form $R(t) = a t^b$ where R is retention, t is time after administration and is ≥ 1 , a is a constant providing the intercept at unit time, and b is the slope of the straight line on the double-log plot, which has a negative value. For some years, the values given by Norris, $a = 0.54$, $b = -0.52$, were utilized. Later C. E. Miller and A. J. Finkel (1966) re-examined the data and made additional radium body-burden measurements on the same State Hospital patients. They arrived at somewhat different constants based on the arithmetic mean of the slopes and a geometric mean of the individual intercepts. These were $a = 0.30$, $b = -0.44$. The range was from $a = 0.18$, $b = -0.22$, to $a = 0.89$, $b = -0.63$. The new average values were used when individual data were not available, which was frequently.

The reports of Miller and Finkel carry an importance beyond the quantitative change in constants. The subtitle of their published paper (1968) is "The Power Function Re-Evaluated." Because of continuing skepticism over the validity of the power function, the work was as much to see if it still held as to get improved values for the parameters. It has held.^(a) The MIT group began using the power function after finding it worked for their data, although with somewhat different constants ($a = 0.54$, $b = -0.52$ [Evans, Keane, and Shanahan 1972]). The beagle dogs at Utah, to be described later, fell in line too. In fact, other alkaline earth elements, such as calcium as represented by ^{45}Ca and strontium as represented by ^{90}Sr , seemed to be retained by functions that were also power functions of time in both man and dog (Rowland 1959). This concept extended even to barium. It may thus be a characteristic of the alkaline earth group of elements or of bone seekers in general.

Obviously for multiple doses, either intravenous or oral, the simple relation needed modification. This was done by the Argonne group, and curves for radium retention after oral ingestion for various periods were worked out on the basis of the power function, with the results shown in figure 1.7, taken from Finkel, Miller, and Hasterlik (1969b).

The picture after a series of fifteen weekly intravenous injections is as one would expect: a series of spikes followed by double-logarithmic decay after cessation (see figure 2 of Finkel, Miller, and Hasterlik 1969b).

All of these metabolic studies were, of course, greatly facilitated by the development of a "whole-body counter" facility at Argonne. This was one of the pioneering efforts for which credit goes largely to Leo Marinelli and Charles E. Miller (see chapter 17).

3: The Argonne Radium Studies

"The Argonne Radium Studies" could of course apply to all of the work with radium done at ANL. But it is reserved for a discrete facet of the work involving man. It encompassed compilation of the clinical effects in a diverse group of the Elgin State Hospital radium patients, the new group of former dial painters, individuals throughout the Chicago area who had received radium as a therapeutic measure from their physicians, and some radium chemists and other

(a) Of course a series of exponentials if close enough in slope can merge into a linear relation on a double-log grid; and the data could be described in this way too. Hence the confirmation is not absolute.

FIGURE 1.7. Log-log plot of radium retention after cessation of oral ingestion. Periods of ingestion are given as factor "F" on the curves. Assumptions were: daily absorption of 1 μCi . Power function parameters: $a = 0.30$, $b = -0.44$. (Redrawn from Finkel, Miller, and Hasterlik 1969b, p. 199. Reprinted with permission of University of Utah Press, Salt Lake City, copyright 1969.)

workers. The clinical evaluation was coupled with measures of the body burden and extrapolation to the presumed original or maximum body burden.

The story has been summarized very well in several reviews (Looney et al. 1955; Finkel, Miller, and Hasterlik 1959; Hasterlik, Miller, and Finkel 1969; and Finkel, Miller, and Hasterlik 1969a,b). One of the most complete but least portable of the summaries is found in special ANL reports devoted to a review of all patients to the date of writing (Miller, Hasterlik, and Finkel 1969).

Note well that these reports are *joint* from Argonne National Laboratory and the Argonne Cancer Research Hospital. The collaboration with the medical community of the University of Chicago and associated institutions was (and is) a very considerable contributory factor, not only in the analysis of the biomedical effects, but in the referral of cases, the retrieval of records, and insights into practices of the past.

The addition of a new group of dial painters was partly the result of a happy coincidence. The investigators knew there had been a Radium Dial Company plant in Ottawa, Illinois, and a Westclox plant in La Salle-Peru, Illinois, and that these had used luminous paint. But attempts to find a significant number of the luminizers were not fruitful. In 1955, long after other facets of the Argonne Radium Studies were well under way, a lady came to see Dr. Hasterlik for whole-body counting and skeletal radiographs. His suspicions were aroused,

and he asked her if she had ever handled radium or been a luminizer. She not only remembered being a dial painter but later provided Drs. Miller and Finkel with a photograph taken outside the factory,^(a) which is shown here as figure 1.8. Later, participants provided other photographs like the one shown in figure 1.9.

FIGURE 1.8. Group picture of dial painters at Ottawa, Illinois, plant taken about 1924, which enabled identification and follow-up. (Courtesy of Drs. Asher J. Finkel and Charles E. Miller, formerly of the Argonne Radium Study.)

Most of these women lived in small towns along the Illinois River, such as Ottawa, Peru, and La Salle, and worked at the plants. The population was quite stable, and by luck the town offices had for many years listed peoples' occupations along with other statistics. Armed with the pictures and helped by the town records, Charles E. ("Chuck") Miller went about finding and interviewing. Each person contacted could usually name others from the picture and knew their status. Eventually he and his colleagues were able to identify ninety-four of the ninety-eight individuals in the group prints! All but two of the individuals involved were traced. Of these, forty-three had died and forty-nine were still living; thirty-nine were considered in good health at a median age of seventy-one years. (The dial-painting jobs were frequently vacation fill-ins for high school students. Thus, the average age at exposure was quite young.) Sixteen of the dead and four of the living persons had had "radiogenic" lesions (Brues and Kirsh 1976).^(b)

(a) Drs. Finkel and Miller obtained the picture by visiting the lady's dressmaking shop.

(b) This paper is an excellent summary of the whole dial-painter saga as well as iatrogenic injections of radium for therapy.

FIGURE 1.9. Interior view showing dial painters at their desks in the Ottawa, Illinois, plant. This, too, helped in follow-up of the group. Note the open trays and close spacing of the workers. (Courtesy of Drs. Asher J. Finkel and Charles E. Miller, formerly of the Argonne Radium Study.)

The Elgin State Hospital group numbered only about thirty cases (but with the advantage of known doses and long follow-up). Therefore, the careful “detective” work of Miller and colleagues added substantially to the scope and validity of the Argonne Radium Studies. The other iatrogenic and self-treated individuals, while undoubtedly numbering in the thousands, were, and are, difficult to find and are a less homogeneous group than any of the others. The total group numbered 293 radium-burdened persons with 208 from the radium industry.

Attempts to find and bring in other patients from the Chicago area have been frustrated by the advanced age and lack of records of the doctors still alive, some of whom not only admit but declare proudly that they gave “hundreds” or “thousands” of radium injections or prescribed radium or radon water. Their faith is attested to by the fact that they included themselves in the meting-out of the nostrum (Hasterlik 1980).

We will consider that the Argonne Radium Studies as originally defined terminated as an entity when the MIT and other groups were consolidated with them in the late 1960s. By that time, some points of similarity and some of difference were compared to what we have described for the MIT-MGH series. These are summarized below:

- a. The radiogenic lesions were qualitatively comparable to those seen in the luminizers and patients from New Jersey, Connecticut, Massachusetts, and so forth, but there seem to be relatively more carcinomas of the sinus and

mastoid regions—especially at later times. This difference, if true, may reside in the absence of MsTh,^(a) for the iatrogenic patients received pure ^{226}Ra , and the luminous compound used at Ottawa had no MsTh in it.

- b. The ANL work, as will be noted, presents the results as radium body burdens—either the estimated maximum burden or the current or preterminal burden—not as calculated radiation dose. The ANL group felt that they could measure body burden accurately, but they eschewed the calculation of radiation dose. They did not like the necessity of delineating critical tissues, critical volumes, and the site of malignant transformation. Since no mesothorium was present in their cases, they were not forced, as was the MIT group, to devise a unit that would present cumulative radiation insult for persons with very different MsTh/Ra ratios. Thus, radiation dose could reasonably be expected to parallel radium burden in the ANL-ACRH cases. Nevertheless, it is awkward to have the two major studies of the day in this very important area use different ways of expressing dose. (Very recently this has changed.)
- c. The dose-response relationship as given for malignant tumors and blood dyscrasias shows an apparent threshold at about $1.2\ \mu\text{Ci}$ estimated maximum radium burden and at a somewhat lower point on the basis of current or preterminal burden. Figure 1.10 reproduces the relationship to estimated maximum radium burden, and figure 1.11 does the same for current or preterminal radium burden. There were 205 suitable cases for figure 1.10 and 218 for figure 1.11. The data points represent blocks of progressively increasing radium burden.

FIGURE 1.10. Incidence of radium-induced malignant tumors and blood dyscrasias in ANL-ACRH series as of September 1967. The incidence is plotted against estimated maximum radium burden in microcuries. Each point represents a block of progressively increasing average maximum radium burden for the subgroups. (Redrawn from Finkel, Miller, and Hasterlik 1969b, p. 222. Reprinted with permission of University of Utah Press, Salt Lake City, copyright 1969.)

(a) ... and its daughters.

FIGURE 1.11. Incidence of radium-induced malignant tumors and blood dyscrasias in ANL-ACRH series as of September 1967. The incidence is plotted against the current or preterminal body burdens measured in each case. The points represent blocks of progressively increasing average radium burdens for the subgroups. (Redrawn from Finkel, Miller, and Hasterlik 1969b, p. 220. Reprinted with permission of University of Utah Press, Salt Lake City, copyright 1969.)

- d. It will be noted that, while there is an apparent threshold, as in the MIT studies,^(a) there is a continuous rise in incidence to 100% in figure 1.10 and no indication of the plateau seen in the MIT cases at about 30% incidence. The apparent difference between the ANL and MGH work in the incidence of tumors above the "threshold" cannot be clarified at this point. It may or may not be real, as will be discussed in the next section. The fact that a threshold, or a practical threshold, appears in both studies is noteworthy.
- e. The ANL reports do not emphasize the x-ray score or plot their data in terms of it. Yet it is clear that they used the system, since it was worked out with great care among the pathologists at the laboratories concerned. Clearly, the roentgenographic changes were given much the same weight in the two studies. Also, many general medical conditions, including such things as gait, an indication of bone destruction in areas such as the hip, were not likely to go unnoticed.
- f. The ANL work discusses epidemiologic bias but does not appear to make formal judgments regarding the epidemiologic suitability of each case or indicate that any have been omitted for this reason. (It does omit those

(a) Evans has calculated the radiation dose associated with the threshold in the residual body burden curve of figure 1.11 as about 2,000 rad. In view of the high M_sTh/Th ratio in the MIT cases, and the probable greater effectiveness rad for rad of M_sTh compared to ^{226}Ra , this figure may be considered in reasonable agreement with the "practical threshold" domain seen in the MIT work.

whose maximum burden could not be estimated even though they have a current burden.)

Further discussion of the work of this group postdates the organization of the Center for Human Radiobiology and will be taken up in the next section.

4. The Center for Human Radiobiology

As the time approached for Robley Evans to retire from full-time duties at MIT, there were in the summed MIT and ANL-ACRH studies some 850 persons identified, potentially exposed, and not yet studied. Additional potentially exposed persons were being identified through physician and hospital records, industrial employment records, and personal contacts. Because of the long life span of humans, a significant fraction of these would be expected to live into the twenty-first century. The great importance of maintaining full study of this invaluable resource led Evans to propose a consolidation of all of the work in a single center. There was detailed consideration of the long-range needs among all concerned including the Division of Biology and Medicine of AEC, the AEC Advisory Committee for Biology and Medicine, the Commissioners of AEC, and the Joint Committee on Atomic Energy of the Congress. The decision was to establish such a center under the title "Center for Human Radiobiology" and place it in the Radiological Physics Division of the Argonne National Laboratory. Dr. Robert E. Rowland was appointed as the first director. Andrew Stehney, Henry Lucas, Patricia Failla, Art Keane, and others identified with the radium work helped to staff the new organization. A field station was maintained at MIT, along with the counting facilities, and another at Phoenix, Arizona, where Dr. Evans made his principal domicile after retirement, and where Mary Margaret Shanahan went also. Others were established in New Jersey and Connecticut to maintain easy contact with the populations of interest. The populations continued to be identified separately, but the overall analysis of data and the central files resided at ANL. Austin Brues moved into the Center on his retirement from the Biology Division. Many others have joined. Unfortunately, Asher Finkel, Robert Hasterlik, and Charles Miller, the principal architects of the Argonne Radium Studies, moved out to other positions. The work of the Center began officially on September 1, 1970, although consolidation moves began somewhat earlier. All new data and new analyses of old data are now reported through the Center (1985).

The work done so far has involved mainly ^{226}Ra and ^{228}Ra , although the Center has had interests also in the ^{224}Ra patients, the Thorotrast patients, and others to be discussed subsequently. The broad name for the Center could subsume most of the efforts in human radiation epidemiology, e.g., plutonium workers, uranium workers, even the populations that received external radiation. However, this has not occurred and may never develop. There continue to be many separate enterprises for these other areas, manned by different groups and somewhat disparate in operation. There is coordination at the Washington level and good communication but no grand consolidation.

Most of the really critical results of work from this Center could be well beyond the cutoff date for this historical review. But a few points of interest can be made now:

- a. It appears that the radium results will be reported both in terms of the radium burden, particularly the initial radium burden calculated from measurements of current or preterminal burden, and in calculated cumulative rad.

- b. Epidemiologic methods of analysis comparable to studies with other types of radiation are being pressed. These include attempts to separate out for analysis groups whose names were obtained through sources largely unrelated to the presence of effects, i.e., were "epidemiologically suitable" in the terminology used earlier by Evans.
- c. Dose-response relationships are being drawn from the combined population and from segments thereof.
- d. Enough carcinomas are now appearing to allow formal comparison of their incidence properties with those of the sarcomas. Recently, many more carcinomas have appeared in those receiving pure radium than in the earlier years.
- e. The objective of having an almost "immortal" organization for following these invaluable cases to conclusion seems reasonably well protected. But it will require constant vigilance and aggressive protection of funding to keep the changing agencies who supply the support from forgetting the absolutely crucial importance of completing the radium saga.

The selected papers outlined below give the flavor of activities in the Center up to the close of the period of our interests.

Rowland et al. (1971) present a dose-response function for fifty-one sarcomas from a mixed population with the form:

$$\text{Incidence} = KD^2e^{-D/D_0}$$

where D is the average skeletal dose in rad to the time of diagnosis (*not* the dose to time of death as employed in earlier reports) and D_0 is 4,700 rad, the apparent threshold. The carcinoma incidence could not be fitted by any continuous function. An earlier report using the quantity of radium initially acquired gave reasonable fits for both types of tumors. But there were more carcinomas in the later analysis, and it should be more reliable.

The appearance times of the sarcomas increase with decreasing initial dose (Rowland, Keane, and Failla 1971) in line with the relationships pointed out earlier by Evans. On the other hand, appearance times of carcinomas do not seem to be related to initial burden.

In further work, the Center has gone to more homogeneous groups. This was made possible by the gradual accrual of more measured cases. For example, Rowland, Stehney, and Lucas (1977) report on a reasonably homogeneous group of female dial workers using radium burden rather than rad as the measure of dose because some had $MsTh$. Among other things, they conclude that linear functions do not describe the dose-response relationship here any better than in the less homogeneous group. A dose-squared exponential of the type described above works best for sarcoma incidence. The head carcinomas were equally well (and reasonably adequately) described by either a linear or a linear-quadratic exponential function. They announced their goal of adding as many more suitable cases to the group as possible.

Other recent papers from the Center have addressed survival time of these same workers using life table bases. (Stehney, Lucas, and Rowland 1978; Polednak, Stehney, and Rowland 1978). Here there are significant increases in modalities other than bone sarcoma, such as leukemia in the earlier years, but mortality ratios from all causes are greater than 1.0 only in the higher-intake groups. In the lower-dose group, the only cause category with a significantly greater number of observed than expected deaths was cancer of the colon. Is this radiation-related?

We can undoubtedly expect further and more detailed work-over of the accumulated data as the Center's work continues. It will require great care to resist the temptation to lump together cases that are really different in order to improve the statistical base.

5. Animal Studies at Argonne

Work with animals continued at ANL on a broad basis after World War II. Although some of it touches on our understanding of radium metabolism and effects, most is pertinent to comparative toxicology of the actinides, fundamental aspects of oncogenesis, or the basis for modeling of bone minerals. Each of these is more pertinent to other chapters of this compendium, and discussion will be deferred.

One paper describing a major radium toxicity study is that of M. Finkel, Biskis, and Jinkins (1969). They conducted experiments with 3,210 CF1 female mice given single intravenous injections. The mice were permitted to live until moribund, each mouse underwent thorough roentgenographic and post-mortem examination, both gross and microscopic. In a later, more extensive radium experiment, radiographic changes were the chief criterion beyond tumor incidence.^(a) The doses covered a wide range. As expected, bone damage and osteogenic sarcoma were the most prominent effects. Interestingly, the bone sarcoma was the most sensitive indicator of damage as compared to other measures. This may contrast somewhat with early bone changes seen roentgenologically in humans without sarcoma development.

There were 711 osteosarcomas in the experiment with some variation in site according to dosage level. Many other tumors appeared, but their incidence was not related to radium dose, and they were therefore not considered radiogenic. The incidence of osteosarcoma was linear with dose leading to the possibility of calculating tumor expectancy for comparison with other species, including man.

The dose-response relationship over the entire range showed sharp changes in slope at 2.5 $\mu\text{Ci/kg}$ and at 20 $\mu\text{Ci/kg}$. The relation appears to be linear between 0 and 2.5 $\mu\text{Ci/kg}$. This contrasts with data from the low-dose domain in man.

D. Other Postwar Radium Research

1. The Utah Beagle Experiment

The philosophy and genesis of this major experiment is described in chapters 7 and 8. Of special pertinence to the ideas considered in this chapter is the information on mesothorium toxicity. Because of the important role of MsTh in the dial painters, it was introduced into the Utah experiment for direct comparison to ^{226}Ra . The results are now reasonably complete. There is no doubt that the shorter-half-life isotope of radium, ^{228}Ra , i.e., mesothorium, is a more effective carcinogenic agent, rad for rad or microcurie for microcurie, by a factor of two to three. The explanation probably lies in the proportion of energy expended on bone surfaces. Even though ^{228}Ra is basically a mineral seeker, all

(a) This later experiment was initiated partly to take advantage of improved animal care facilities and decrease of intercurrent respiratory infections. The bone tumor incidence was higher per unit dose than in the early experiment, perhaps because the decrease in intercurrent infections cleared the way for expression of the cancers.

radium isotopes reside initially in part on bone surfaces and only gradually move into the mineral phase by exchange with calcium. Because of shorter half-lives, ^{228}Ra and its daughters expend a larger portion of their energy near the endothelial cells near to the bone surface. These cells are thought to be one of the prime targets in oncogenesis by bone-seeking radionuclides. Furthermore, ^{228}Th is formed from ^{228}Ra . Thorium is a surface seeker. Any ^{228}Th formed will remain at the surface or be translocated to bone surface. Finally, the ^{224}Ra formed next in the decay series has a relatively short half-life and, being formed in large part at the bone surface, will also expend a considerable part of its energy near the target cells. Thus, at least a qualitative explanation appears for the greater effectiveness of MsTh on a rad-for-rad basis and for the important role of MsTh when present in the dial painters.

Another interesting finding in the radium portion of the Utah beagle experiment is the production of intraocular melanomas from ^{226}Ra and ^{228}Ra (Taylor et al. 1969). The latent periods were long. This is reminiscent of the ocular changes described by Norris in his animals in the Plutonium Project work (see section V B). It has not appeared in man.

2. The Davis Beagle Study

A second major beagle study was initiated at the University of California at Davis in the mid-1950s. This experiment was designed primarily to evaluate the relative toxicity of ^{226}Ra to ^{90}Sr . The dosage levels of ^{226}Ra were similar to those employed in the Utah study. But the dose was divided into eight equal semi-monthly intravenous injections to simulate more closely the human exposure situations. Since the Radiobiology Laboratory work at Davis used radium primarily as a bench mark, and the comparative approach was paramount, further discussion will be postponed to later chapters.

3. The New Jersey Dial Painters

For a while during the 1950s, separate financing was provided by AEC through its New York Operations Office (NYO) for follow-up of the classic population of luminizers in New Jersey. This, called the "Radium Research Project," resided in the Department of Health of the State of New Jersey. This department had been interested in the subject from the very start as described in section III. The project director was Samuel C. Ingraham II, M.D. Among the collaborators was Theodore Blum, who helped to start the whole radium saga, although he died quite soon after the project started. Some films taken by Blum and by Martland are included in the analysis.

The object seemed to be epidemiologic follow-up. This undertaking was during the days of rapid multiplication of projects under AEC and appears to have been organized primarily to give the original New Jersey group an identity of their own. However, the publications from this group are not numerous. I find only two, an atlas of roentgenographic findings (Barrer et al. 1963), which gives no bibliographic references to other publications, and a report from the New York Operations Office of the AEC (NYO-2181-3). Roentgenographic findings are presented in detail for sixteen cases. While there are probably other publications of the same sort, it was not long before the New Jersey cases were being described again in the MIT reports as they had been in earlier years. Thus, it appears that the period of independence was not long enough to carry forward a full-blown epidemiologic study. The New Jersey cases seem to be adequately

described in the MIT reports, although the MIT group would be the first to say they had not attempted a formal epidemiologic approach.

4. Luminizers in Czechoslovakia

Jan Müller (1970) has reported on a population of luminizers in Prague and vicinity. This group used primarily a paint containing ^{90}Sr and its daughter product ^{90}Y . But prior to this, there was some use of a paint containing ^{226}Ra .

Under the auspices of the International Atomic Energy Agency, Müller has measured body burdens of both ^{90}Sr - ^{90}Y and ^{226}Ra using both urinalysis and whole-body counting. In contrast to most other studies, his concentrated on hematological changes with special emphasis on chromosome aberrations and their possible significance in leukemogenesis. Since the principal thrust of this study is on strontium, details will be reserved for chapters 8 and 13.

5. On "Hot Spots," Micro- and Macrodistribution

As individual samples of bone began to come in from autopsy and exhumation cases, it became apparent that the radium content was not the same in different bones. This fact was evident even in pre-World-War-II days as already described, but the story expanded considerably in later years. For example, the long bones lose radium at a slower rate than the skeleton as a whole and, thus, have higher contents long after administration. The specific activity in the vertebrae is different from that in the skeleton as a whole. This has a direct bearing, of course, on the calculation of dose and correlation of dose with site of tumor formation or other skeletal change. Examples are shown in the MIT annual reports (MIT 1965, 1966, 1967, 1968). The same phenomenon has been found in other populations and in the animal work. But tumor incidence does not seem to be correlated well with these differences in macrodistribution, and the average dose to skeleton has been applied in general use (see also chapter 16).

A second variation is in microdistribution. As soon as the technique of autoradiography became well established, and microscopic sections of bone could be viewed by both the conventional light microscope and by the picture the deposited radioisotopes made on special thin photographic films applied to the sections, it was apparent that there were areas of higher concentration and areas of more or less background concentration. The former were termed "hot spots." The relation of these to dosimetry had been discussed and tested widely. Also, investigation of the meaning of these variations in microdistribution to the mineral metabolism of bone has led to a whole new domain in the physiology and biochemistry of bone.

Suffice it now to refer the reader to a comprehensive review of alkaline earth metabolism in bone prepared by a task group of the International Commission on Radiological Protection (ICRP) under the chairmanship of John Marshall, Argonne National Laboratory. It was published as both ICRP Publication 20 (ICRP 1972) and in the journal *Health Physics* in 1972 (Marshall et al. 1973).

6. Radium Content of Water, Food, and of Individuals with No Known Occupational Exposure

Interest in the normal radium content of unexposed individuals and of their food and water supplies began in earnest in the late 1940s. Two reasons can be cited as paramount. First, as the knowledge of effects in occupationally exposed

individuals accumulated, it was natural to speculate on what concentrations might be present in persons with no known exposure, especially to see if they approached the levels at which effects occurred in the workers. Second, it became necessary to suggest factors by which the occupational limits should be reduced when large populations were concerned. A factor of ten to one hundred was suggested, which would have meant concentrations of 4 or $0.4 \mu\text{Ci/l}^{(a)}$ of water.

As early as 1934, Botstet had reported on the radium content of natural waters in the Pittsburgh area, and in 1939 and 1942, Krebs, who worked at the Kaiser-Wilhelm Institut für Biophysik, Frankfurt a. M., gave figures for both the waters of Frankfurt, Germany, and for humans and animals living in the area (Botstet 1934; Krebs 1939, 1942). Leo Marinelli in his Janeway Lecture (Marinelli 1958) pointed out that the possible population limits in water are lower than the radium contents reported for the Frankfurt and Pittsburgh water supplies. Hursh and Gates (1950) point out in addition that the upper range of Krebs's figures for body burden (in eighteen deceased individuals) is within 40% of the recommended maximum permissible body content for *occupational* exposure.

To check on the older figures, Hursh and Gates analyzed the bodies of twenty-five adult individuals (cadavers from the Rochester Medical School anatomy course) and six stillborn infants. The procedure of ashing the whole body and measuring the radium by collection of radon was superior to the in-vivo measurements possible at the time on unexposed individuals (i.e., it was before the whole-body counter was perfected). The measurements of Hursh and Gates showed only about 1/100 of the average value reported by Krebs,^(b) i.e., about 1.2×10^{-10} g versus Krebs's figure of 1.4×10^{-8} g average.

This finding led Hursh to an extensive and systematic study of the radium content of drinking water supplies from communities around the United States. Were the European waters enough higher to account for the factor of one hundred difference between their figures and those of Krebs? Carboys were shipped to forty-one cities representing about one-fifth of the population of the United States and were returned to the Rochester Laboratory for measurement. A few of the results are given in the Hursh and Gates paper cited; more are shown in a University of Rochester Atomic Energy Project Report published in 1953 (Hursh 1953). The average value was only $0.04 \mu\text{Ci/l}$.

Although some areas of Germany, like some areas in the United States, do have water with much higher radium content than the average, and Frankfurt is not far from one such area (Badgastein), it seems unlikely that the Krebs body-burden findings are correct.^(c)

(a) We would now use picocuries (pCi) as the unit.

(b) The paper by Hursh and Gates is replete with details not only of methodology but of possible correlations and extrapolations and is highly recommended as an example of how good internal emitter research should be done and reported.

(c) Since Krebs moved to the Army Medical Field Research Laboratory at Fort Knox, Kentucky, at about this time, any rechecks had to depend on the work of others. In a personal memorandum written October 28, 1949, Krebs states that Janitzky and coworkers had checked the radium activity of Frankfurt water at 0.3 to 0.5×10^{-12} g/g in contrast to the Hursh figures of about 10^{-16} g/g water. So there may be a real difference in the radium content, but it is not clear that this difference can account for the differences in body burden reported.

The next step was, of course, to examine the contribution made by food. This was taken up in the United States by one of Dr. Hursh's students, Paul Shandley, and in Germany by Muth et al. and Rajewsky et al. (Shandley 1953; Muth et al. 1957; Rajewsky et al. 1957). The average for the United States diet was about $1 \mu\text{Ci/day}$, which Marinelli points out is consistent with the $1.6 \mu\text{Ci}$ derived by the Chicago group (Stehney and Lucas 1956) from analysis of excreta. The figures from Germany were higher by factors of around ten, which probably reflects the higher radium content of the environment. In either case, the contribution from food is obviously quite small.

A final consideration from these studies is what chance there is that the normal incidence of osteosarcoma in man comes from the radium burden derived from natural sources. This is reviewed by Hursh and Gates. With an average measured body content of about 1×10^{-10} g and the knowledge that 5×10^{-6} g can be associated with minimal skeletal changes, the ratio is about fifty thousand to one, a far cry from accounting for the natural incidence of bone cancer.

7. Examination of Areas with High Radium Content in Drinking Water

The existence of waters with high radium and radon contents has been known for many decades, in fact for over a century in the case of radon. Many of the spas of Europe and the United States are built around such sources. But the principal interest in these is the inhalation of radon gas. This will be discussed in chapter 3. Obviously, the water supply in such areas is frequently high in radium, and some attempts have been made to measure possible effects on the indigenous population. However, the population indigenous to the spas is too small and too heterogeneous to support a reliable study.

It was therefore of great interest when it became apparent that some Illinois communities in the vicinity of Chicago had been drinking waters for half a century close to, or above, the allowable population exposure for ^{226}Ra in water and that these had, in addition, some ^{228}Ra . The total population appeared to be potentially over 100,000 individuals. The interested staff at Argonne National Laboratory zeroed in on this opportunity first with careful measurements of the water and the body burdens, and second with searches for above-normal incidence of bone cancer. They (Lucas and Ilcewicz 1958) found that the drinking water supplied by deep wells of many small towns in about half the counties of Illinois was up to one hundred times above the average found by Hursh for larger city supplies. These figures were summarized by Marinelli (1958). The body burdens in Chicago, which uses water from Lake Michigan that is very low in radium, and in the small towns differed by a factor of about fifteen. The tumor-incidence figures showed some interesting trends, some beyond the standard error of one group compared to another. But on the whole these were not beyond the uncertainty of the basic incidence figures. This is partly due to the fact that only twenty-seven cases of bone cancer were uncovered by the survey. It was probably due also to the fact that the really high radium contents of water were in the smallest communities. Thus, the change in incidence, if any, is masked by the statistical uncertainties. Marinelli and others have urged addition of populations from neighboring states with similar geological formations. These, if added and studied carefully, could greatly improve the statistics, since the total population might then be over two million. But the changing times with greater population mobility even in small towns like those under study, and the enormous effort needed to do the job properly, seem to have discouraged significant further work. Not much new has appeared in the recent

literature. Other problems and other populations have come along to deflect the efforts of those concerned. Thus, the work, while bringing forth much interesting information, did not show the increase in bone cancer that many at first considered almost inevitable. It also shows that isolation of a single factor from among the many impinging on a population is a difficult and extremely demanding exercise.

The consideration of radium in water is inextricably linked to occurrence and possible effects of radon. For convenience, the possible exposures from radium-radon-containing waters at hot springs, spas, and related sources are taken up in chapter 3. In a sense, that discussion is an extension of that in the paragraphs above.

VII. Radium-224

A new domain in American biomedical research with the isotopes of radium, and one with a strong international flavor, began in the 1960s. All of our discussions so far in this chapter have concerned the most commonly employed isotope of radium, ^{226}Ra , and to some extent its decay products, plus some necessary consideration of ^{228}Ra because it occurred as a contaminant in the luminizing paint. The new domain concerns ^{224}Ra , a decay product of ^{228}Th . "Chuck" (Dr. Charles W.) Mays at the University of Utah had a German research assistant. One day she called his attention to some papers in the German literature she had seen in the library. They described the use by a country doctor of a nostrum called "Peteosthor"^(a) for the treatment of tuberculosis, ankylosing spondylitis, and related maladies in northern Germany. A young German pediatrician at the University Children's Clinic in Göttingen was asked in 1948 to investigate these treatments, partly because they involved many children. His name was Heinz Spiess. He found that the nostrum was useless for the diseases being treated, nor did it have any effect on tubercle bacilli in vitro except at very high concentrations (Spiess 1978). But already clinical signs of radium toxicity were showing in the patients.

Here, it seemed, was a whole new population distressingly similar to the thousands of individuals who had received ^{226}Ra for "therapy," but with a radium isotope of much shorter half-life, only 3.6 days. Mays wrote immediately to Spiess for reprints. Bob Rowland at Argonne Laboratory had the Spiess work translated and circulated in the ANL translation report series. Mays invited Spiess to present his findings at the next Sun Valley symposium sponsored by the Utah project to be held in September 1967. Spiess came and delivered, in excellent English, a superb summary of the biomedical effects and the characteristics of the population (Spiess 1969), which was something of a bombshell. It was entirely new information to most of the audience.

But the project needed some help with dosimetry and physical problems. So Mays, the physicist turned biophysicist, went to Germany for a month between meetings he was already scheduled to attend in Europe. Thus started a collaboration that has flourished ever since with yearly visits between Salt Lake City and Munich, where Spiess had moved soon after the work was well established. To a

(a) The preparation was a combination of ^{224}Ra , colloidal platinum, and eosin. The platinum and eosin were alleged to facilitate access of the therapeutic agent, ^{224}Ra , to the areas of inflammation and thus action on the tubercle bacillus itself. It was prepared by the Buehler firm in Braunschweig, Germany.

degree, we saw here a repeat of the physicist-biologist-physician collaboration that worked so well in operating the MIT project, and indeed in numerous AEC laboratories during the postwar years.

The story has been told well in readily available literature already cited, including a narrative historical summary by Spiess (1978). Hence, we will present primarily a summary-type review.

A. The Population

The injection of ^{224}Ra (Th-X) occurred in the years 1944 to 1951 in hospitals primarily in northern Germany, especially one at Hildesheim presided over by a Dr. Troch, who was championing Peteosthor. The patients ranged in age from one to seventy years. The total number in the original group was about 2,000; of these, 802 had been checked at the time of Spiess's Sun Valley paper; 206 of these were youths under twenty-one years old. A 1980 summary of the results is given in tables 1.2 and 1.3 prepared by Mays (1980).

TABLE 1.2. Summary of ^{224}Ra Patients in the Spiess Follow-Up—Average Date of Injection, About 1950

	Age at First Treatment		
	1-20 Years	Adult	Total
Total traced patients	218	680	898
Deaths	77	333	410
Bone sarcomas	36	18	54
Cancers of soft tissue	9	54	63
Leukemias	0	3	3
Panmyelosis or "anemia"	1	4	5
Kidney diseases	6	49	55
Liver diseases	1	19	20
Exostoses (benign)	28	0	28
Teeth breaking off	23	13	36
Cataracts	11	25	36

Source: Reset from Mays 1980.

Since the nostrum was prescribed for the treatment of tuberculosis, and some of the war and early postwar years are involved, we would expect to find a large number of younger patients, as indeed was the case. This, plus the generally poor nutritional status of the population, particularly at the outset of treatments, makes this set of cases qualitatively different from the dial painters and iatrogenic cases in the United States. But the analysis seems to have been able to cope quite adequately with this difference. Indeed, it adds many points of special interest because of the opportunity to see effects on growing bone and in a young population.

The use of ^{224}Ra in children was stopped about 1951, and for all forms of tuberculosis soon thereafter. But the population is available for long-term study.

Radium-224 continues to be used in Germany but is now limited largely to patients with ankylosing spondylitis and to use of pure ^{224}Ra . (This malady is treated in England by x rays and has provided another population for study

TABLE 1.3. New Cases Between 1974 and 1980

	Age at First Treatment		
	1-20 Years	Adult	Total
(Total living and dead patients)	(218)	(680)	(898)
Deaths during the last 6 years	11	83	94
Bone sarcoma cases	0	0	0
Cancers of soft tissue	4	16	20
Leukemias	0	0	0
Panmyelosis or "anemia"	0	0	0
Kidney diseases	2	16	18
Liver diseases	0	1	1
Exostoses (benign)	0	0	0
Teeth breaking off	6	6	12
Cataracts	4	12	16

outside the scope of this book.) The current doses are, however, much smaller than those given earlier (Schaes 1978), and toxic effects will probably be much less evident.

The observation period of the initial population is now about thirty years.

B. The Dosages

Multiple injections were given of from 8 to 70 μCi each. Total amounts were 40 to 5,000 μCi . The duration of injections was from a few weeks to a few years.

The medical records of the patients give the alpha-particle ionization of ^{224}Ra and its daughter products in an old unit, esE (*elektrostatichen Einheiten*), whose translation to microcuries required considerable work (Spiess and Mays 1970). By acquiring sample injection solutions from the same firm made by the same techniques of separation as those injected into the patients, they were able to establish a working relationship:

$$1,000 \text{ esE (stated)} = 140 \mu\text{Ci } ^{224}\text{Ra (injected)}$$

Another problem was the conversion to skeletal and local dose in rad, which the investigators felt compelled to do in order to compare effects in different age groups, growing skeletons versus mature skeletons, etc. Some of the subjects grew considerably during the period of their injections, and it was necessary to apply growth statistics from standard growth tables for German children unless individual data were at hand. The ICRP's "Standard Man" was not applicable to these situations.

Further, there arose the question of what mass to compute the dose over. Radium-224 is metabolized chemically like all radium isotopes. The patterns described earlier for ^{226}Ra hold just as well for it. Thus, the early deposition is in soft tissues and on the surfaces of bone. Later it leaves the soft tissues, and gradually the surface deposits in bone migrate into bone mineral. But because of its much shorter half-life, a higher portion of the energy imparted to tissue by ^{224}Ra is in the surface layers of bone, i.e., the endosteal cells, and in soft tissues in general. Spiess and Mays (1973) contend that the suitable critical tissue or critical volume must be the bone surfaces. On this basis, the rad dose to bone surfaces from ^{224}Ra is about nine times that based on average skeletal dose, which is used for expressing dose from ^{226}Ra .

In terms of relative effectiveness using the same base for calculation (i.e., average skeletal dose), Spiess and Mays (1970) calculate that the lowest skeletal dose causing death with ^{224}Ra is only 90 rad compared to about 1,200 rad for the dial painters (see section VI B).

Plots of the dose-response relationship for bone sarcoma appear to be linear, and this has allowed Mays to make risk estimates from the data. But the range of data and scarcity of sarcomas in the lowest dose domains do not allow a reliable distinction between a linear nonthreshold relation and others, including a "practical threshold," at low doses.

C. The Effects

Bone tumor incidence is high in the ^{224}Ra population (cf. table 1.2). The doses are high and quite effective. If one uses average skeletal dose, ^{224}Ra is much more effective than ^{226}Ra , but if one uses the relative endosteal-cell doses, the effectiveness of ^{224}Ra more nearly equals that of ^{226}Ra , or at least is close to the error of the measurements (a factor of thirteen versus a factor of nine).

In addition to production of cancers, there is marked growth retardation, presumably due to inhibition of bone growth, tooth breakage and other dental problems, and the array of roentgenographic changes described earlier for ^{226}Ra , e.g., damage to epiphyseal cartilage, growth-arrest plates, changes in spongiosa, and irregular ossification. Also, there seem to be many benign osteochondromas.

It is clear that these cases show many more effects in soft tissue than does ^{226}Ra (Spiess, Gerspach, and Mays 1978). These include kidney disease, soft-tissue neoplasms of considerable variety, and possibly liver damage (although hepatitis was endemic in the hospitals, and this is therefore not clear-cut). Also cataracts appear in considerable number and include many individuals in the age group where spontaneous cataract is very rare. It seems unlikely that the soft-tissue neoplasms are radiation-induced. The problems with the liver changes have been mentioned, but both these and the kidney changes are a function of dose. The cataract incidence is so unusual that it appears clearly to be associated with the therapy.

D. On the Effect of Dose Protraction

In an interesting paper given at the Hanford symposium, Radionuclide Carcinogenesis, in May 1972, Spiess and Mays (1973) present calculations that they conclude show that protraction of dose *increases* the effectiveness of ^{224}Ra . This is exactly the opposite of the usual effect seen with x rays and other low-LET (linear energy transfer) radiation. It also differs from that described for some non-bone-seeking alpha emitters such as ^{210}Po (Stannard, Blair, and Baxter 1964; Stannard 1973). While Spiess and Mays offer several plausible explanations, and it has been confirmed in animal experiments (Müller et al. 1978), the phenomenon requires further study, particularly in view of its important bearing on standard setting.^(a)

E. Comment

Research with ^{224}Ra is continuing quite actively. This is partly because it is involved in the Thorotrast cases to be discussed in chapter 4, as well as in its

(a) More recent work confirms and extends these observations.

own right. Some recent papers are cited below. In 1974, an international symposium on ^{224}Ra and Thorotrast was held at Alta, Utah. Its published papers occupy an entire issue of *Health Physics* (Vol. 35, Number 1, July 1978). In addition to the papers by Spiess et al. and Müller et al., there are discussions of the history of the use of ^{224}Ra , its radioactive properties and biological behavior, preparation of solutions, and so forth.

Spiess and Mays (1979) have described the liver diseases in detail and shown a marked contrast between ^{224}Ra and Thorotrast.

Clearly, this recent addition to the scope of radium research has provided valuable new information and valuable opportunities to test ideas developed earlier. It is an active current field internationally and should be followed carefully by the interested reader.

Mays (1980) has prepared an informative chronology of the development of the story of ^{224}Ra ; it is shown below as table 1.4. Note the several items we could not discuss here.

TABLE 1.4. Some Dates in the History of ^{224}Ra

1902	— Thorium-X (^{224}Ra) discovered by Soddy and Rutherford.
1912	— Arthritis patient died because of ^{224}Ra injections.
1944	— Radium-224 therapy of TB and Ank. Spond. started by Troch.
1948	— Heinz Spiess asked to investigate ^{224}Ra therapy. ^{224}Ra deposition same for "Peteosthor" or pure ^{224}Ra .
1949	— Spiess showed Peteosthor ineffective against TB.
1950	— Spiess officially protested against Peteosthor.
1951	— Peteosthor stopped in children and TB adults. Treatment of Ank. Spond. continued, but with pure ^{224}Ra .
1952	— Spiess began first follow-up.
1956	— Spiess published the first bone sarcoma cases.
1963	— Radium-224 injected into 14 beagles, University of Utah.
1964	— C. W. Mays learned of Spiess results.
1967	— Spiess presented results at Sun Valley Symposium.
1969	— Mays began annual work sessions with Spiess. Converted esE to μCi (1000 esE = 140 μCi ^{224}Ra). Calc. av. skel. dose (1 μCi ^{224}Ra \rightarrow 14 rad to adults).
1970	— Spiess and Mays published their results in <i>Health Physics</i> . Radium-224 therapy became less frequent. Hug and Schales began new study of additional patients.
1972	— Radium-224 effectiveness increased with protraction in man.
1974	— Alta Symposium: Protraction effect confirmed in mice. Skeletal effects and soft tissue effects presented. John Marshall calculated endosteal dose to adults.
1975	— Radium-224 results used to predict ^{239}Pu risk to bone.
1976	— Neuherberg Symposium: Benefit and risk of therapy. Similar appearance times for bone sarcoma and leukemia.
1977	— Gossner and Wick continue the studies of Hug and Schales. DOE approved the injection of 126 beagles with ^{224}Ra , University of Utah.
1978	— Radium-224 injected into 120 mice at University of Utah.
1979	— In \sim 1000 new low-dose patients, 2 skeletal sarcomas found by R. Wick versus a life-span prediction of 3 cases based on the linear model of Spiess and Mays for an injection span of 2 months.
1980	— No new bone sarcomas since 1974. Soft tissue cancers are increasing. No new leukemias since 1957. Kidney diseases are increasing. Tooth breakage is increasing. Cataracts are increasing. What is the effect of the platinum in the "Peteosthor"?

Source: Reset from Mays 1980.

The ^{224}Ra data have recently contributed to estimation of risk from plutonium in man (cf. later chapters).

VIII. Summary and Commentary

Radium, primarily ^{226}Ra , has been a source of healing and palliation of cancer and other ills since not long after its isolation from pitchblende by Marie Curie. The number of human beings and animals benefited by the penetrating gamma radiations from radium exceed by far the number harmed by the effects of radium taken internally. Nevertheless, it is this latter aspect, the effects of the highly ionizing alpha particles inside of cells and tissues, that comes within the purview of this chapter and this book.

Unlike x rays, whose potential for harm became apparent very soon, it was not until the 1920s, through the dolorous story of the luminous dial painters from World War I and the numerous individuals who took or received radium as a therapeutic nostrum, that the potential for lethal damage from deposited radium became apparent. At the outset, there was the fortunate, indeed extraordinary, series of coincidences in the meeting of a perceptive dentist (Blum), conscientious and talented physicians (Martland and Hoffman), a good chemist (Gettler), and, later, a dedicated and talented physicist (Evans) around the saga of the dial painters. However, the unraveling of cause and effect and quantitation of dose and effect is due largely to the life-long devotion of Robley Evans and his colleagues at the Massachusetts Institute of Technology, and, in more recent years, to investigators at the Argonne National Laboratory near Chicago (The Argonne Radium Studies and the Center for Human Radiobiology).

Through fortunate continuation of both interest and funding, the biomedical effects of radium in man represent our longest and most thorough set of observations of the effects of internally deposited radioactivity. The work must continue into the twenty-first century in order to study all of those with identifiable or strongly suspected body burdens of significance.

A maximum permissible body burden of radium for occupational exposure was set just before World War II and has remained viable ever since. For this and other reasons, radium became, and has remained, the bench mark for gauging the effects of many other radionuclides, especially those that deposit in bone.

By virtue of its position as a bench mark, radium was used in extensive animal experiments, both during World War II (primarily at Chicago and Rochester) and since (at Argonne National Laboratory, University of California at Davis, University of Utah, and similar large projects described in later chapters). In the process, much was learned about the metabolism (i.e., pharmacokinetics) of radium and of its effects that could not have been learned at the lower levels of intake characteristic of the experience with humans. Yet, despite enormous efforts in both clinical and experimental settings, there is still uncertainty regarding the details of the dose-response curve. Much of the clinical information points to a level below which bone cancer does not develop, but this does not mean that more subtle effects are absent.

Part of the problem has been that few of the occupational exposures and not all of the clinical cases involved pure ^{226}Ra . The majority had other isotopes of radium or some of the decay products mixed in. This made the dosimetry more complex. This, plus a lack of knowledge of the exact nature and location of the

cells at greatest risk for bone cancer development, means that resolution of detailed quantitative aspects will require yet some time and major advances in cancer biology.

A prominent feature of the research on radium has been the finding of new exposed populations. The growth and development of these is detailed in the chapter. One of the most prominent "new" populations was a group in Germany, primarily children found just after World War II, who had been given a shorter half-life isomer of radium, ^{224}Ra . The collaboration of German investigators and the group at the University of Utah (especially C. W. Mays) has produced a dosimetric and epidemiologic little brother to the work with ^{226}Ra , ^{228}Ra , and the other radionuclides involved with the dial painters, radium chemists, and many of the unfortunates who dosed themselves with preparations such as "Radithor."

There was naturally considerable interest in the amounts of radium and associated elements in water and in food. It soon became apparent that the amounts in water could vary over a wide range. Some well waters in the central United States and in Europe have concentrations far above the average. The waters of the various therapeutic spas are especially high. Yet, no clear relationship between health effects and exposure to or drinking of these waters has been demonstrable. The population sizes are too small and the exposure times to the highest concentrations too short. Nevertheless, there are those who advocate more formal and detailed study of these populations in the future.

Useful summaries, particularly of recent work, are included in the chapter. Particular note might be taken of Jee (1976), UNSCEAR (1977), and a partial summary of radium toxicity studies produced by the Bureau of Radiological Health, U.S. Public Health Service (Chiacchierini et al. 1970).

Radium could probably be categorized, as Peter Alexander once characterized x rays, as a "double-edged sword," i.e., a source of therapeutic value when used one way, a source of deleterious, even fatal, effects when used in another. In this case, it is the penetrating gamma radiation from sealed sources of radium that supports the genuine therapeutic uses of radium, while it is the short-range highly ionizing alpha particles that underlie the untoward effects of radium deposited in the body.

Capsule Chronology

- 1824** Uranium described in Gmelin's Handbook.
Much animal toxicity work done thereafter.
- 1860** Uranium first used in homeopathic medicine for treatment of diabetes. There follow over fifty years of clinical use. Animal toxicology work parallels the clinical uses. Much effort expended on trying to use uranium in animals as model for kidney changes caused by nephritis in man—largely unsuccessful.
- 1895** Rutherford shows that "uranium emanation" has the spectral line of helium.
- 1896** Becquerel demonstrates the radioactivity of uranium.
- 1904** Rutherford shows that alpha particles are helium atoms and works out the natural decay series.
- Next three decades** Sporadic work on toxic effects in cells. Much work on effects on blood chemistry, various physiological systems and organs, histological changes, repair processes. Tolerance demonstrated in 1920s.

WORLD WAR II

- 1942** Realization that enormous quantities of uranium would have to be handled in the Manhattan Engineer District work. Tracer work at Berkeley (Hamilton).
- Late 1942** Beginning of biomedical work in Chicago at Michael Reese Hospital and later the Metallurgical Laboratory (Tannenbaum, Singer, Barron, and colleagues). Effects on cells as well as whole organisms.
- 1943** Organization of extensive program at University of Rochester, which emphasizes acute toxicology at the start but also goes deeply into biochemical mechanisms, complexing, and an extensive program of inhalation toxicology, which is detailed in chapter 9. All varieties of uranium compounds, several species of animals, and all types of effects are studied. (Hodge, Neuman, Rothstein, Voegtlin, Maynard, Stokinger, Dounce, and scores of colleagues).
- 1942-1947** Attempts to devise sensitive tests for kidney damage in man. Determined that only a battery of tests is reliable.
- Late 1940s** Work at Chicago on higher-specific-activity isotopes of uranium begins. Reported postwar.
- 1948** Six patients at University of Rochester who received uranium for kidney function tests described (injections done earlier in the war). Threshold for kidney damage described.

POST-WORLD WAR II

- 1949 and 1953** Rochester work with uranium done during war years published in four-volume set under National Nuclear Energy Series (Voegtlin and Hodge).
- 1951** Chicago work on uranium published as volume in National Nuclear Energy Series (Tannenbaum).

Preceding Page Blank

- 1951 et seq. Eleven-year chronic inhalation experiment begins at Rochester in 1955. Five years of exposure, six years of postexposure observation and measurement. Pulmonary lymph nodes are necrotic and full of uranium. Lung damage similar to that seen with plutonium. At longest times and highest doses lung cancer demonstrated in dogs but not monkeys.
- 1949 et seq. M. Finkel, at Argonne National Laboratory, follows up on relative effectiveness of ^{233}U compared to ^{226}Ra in mice. Publications in 1950s et seq.
- 1950s Animal studies at Oak Ridge on uranium compounds of most concern in their operations.
- 1950s Cooperative study of eight patients between Massachusetts General Hospital-Boston Veterans Administration Hospital and Oak Ridge National Laboratory. Mid-1950s: metabolism found similar to animal studies.
- 1955 Oral administration of uranium to man by Butterworth, 1955, with marked effects; by Hursh et al. 1969, with lower dose and no measurable effects. Metabolism found similar to that in animals.
- 1950-1970 Depositions in tissues from industrial exposures checked by bioassay of excreta and whole-body counting, also from autopsy material. Amounts of uranium in lung of man far lower than predicted from metabolic data and air sampling results.
- 1950 et seq. Evidence for kidney damage in industrial exposures much less than anticipated. Leads to postulate that man is significantly less sensitive to toxic effects of uranium than experimental animals. First discussed at New York symposium in 1958; expanded at Arlington symposium in 1975.
- 1973 Key reviews by Hursh and Spoor, Spoor and Hursh.
- 1978 Uranium Registry finally established.
- Late 1970s-1980s Bona fide epidemiologic study of Tennessee Eastman plant workers exposed during World War II now in progress (late 1970s and early 1980s). Utilizes personnel data obtained during war and current or recent past determinations of effects.

Chapter 2

Uranium

Overview

This chapter reviews the highlights of a research effort referred to near its completion as "the most comprehensive experimental investigation of an industrial poison ever carried out . . . in such a short time" (Voegtlin and Hodge 1949). Probably a greater effort has now been expended on plutonium, but the time span is quite different.

Much "basic science" that came out of the uranium work can only be alluded to in this chapter. Also, several major aspects, which involved primarily inhalation toxicology, are reserved for the large section on that topic (chapter 9). Conversely, one of the largest and longest inhalation experiments is taken up here because it provides a fitting extension of the work done in the fever heat of the war effort.

This chapter is unique in that much of the concern is with chemical toxicity rather than radiation effects. From time to time, other long-lived radioelements have been regarded as carrying a component of chemical toxicity along with radiation effects. Plutonium was so regarded in the early days, and there is still some residual musing on the idea. Thorium in Thorotrast is another candidate. But neither these nor others suggested have demonstrated the clear-cut chemical (nephrotoxic) action of ^{238}U and natural uranium. Yet, there is a radiation component in uranium toxicity if enough time is allowed or if mixtures enriched with the shorter half-life uranium isotopes are used.

To conserve space, this chapter must leave out many interesting and worthy contributions, but it is hoped the presentation has captured the flavor of the research as well as its fervor and will show how concentrated work on practical goals can still provide valuable insights into chemical and biological mechanisms, some of which have grown into now discrete and sophisticated fields of inquiry. Some of our contemporary problems with nonradioactive substances deserve an attack similar to that organized around uranium, but the will and the organization seem to be lacking.

I. Introduction

The research with uranium, both natural and the shorter-lived more radioactive isotopes, was primarily directed toward the prevention of occupational over-exposure. Some of the dirtiest operations in the Atomic Bomb Project were in the handling of uranium ore and the several uranium salts prepared in the passage from ore to nuclear fuel. In one step, the production of "green salt," at least one worker became so immersed in his work that he was known as "The Green Hornet" after a popular cartoon character of the day. (Fortunately absorption was minimal.)

These conditions were not in callous disregard of the health of the workers but because of the pressures of the war to do things in a hurry. A major effort was mounted in uranium toxicology, primarily natural uranium. The results were applied to industry as quickly as they could be, and in general, it appears, in time to prevent a major long-term disaster for the hundreds of workers involved.

This chapter concerns this research. Applications to inhalation problems, except for one chronic exposure experiment, and to standards are deferred to chapters 9 and 16, respectively. Environmental contamination problems with uranium are considered in chapter 11.

It has been customary to state that little was known about the biological effects of uranium when the decisions were made to develop the atomic bomb; organize the Manhattan Engineer District (MED); and proceed to mine, handle, and store quantities of uranium orders of magnitude greater than ever before. Actually, a great deal of work had been done. Hodge (1973), in his monumental compendium, "A History of Uranium Poisoning (1824-1942)," has over four hundred references in the bibliography. This author has close to two hundred cards on work before 1942 accumulated without any special effort to reach into the early history. Uranium was used empirically in medicine, and its acute effects on the kidney were fully appreciated in the late nineteenth century. In fact, uranium was used widely in experimental medicine to induce in animals a nephritis that it was hoped would duplicate the disorder seen in man. In addition, there is a large literature on the effects of uranium on lower organisms. There was also some crude information on its acute toxicity in higher organisms by the time the MED began.

Why then was it felt necessary to mount a major effort on uranium toxicology at the beginning of the MED effort? First, it was known that uranium was toxic, but there was essentially no information on what levels might be innocuous or "tolerated." Second, the route of entry was most likely to be inhalation. Almost all of the earlier work involved parenteral administration. Third, many new compounds were expected to be involved. Fourth, the number of potential exposed individuals was legion compared to any previous operations, and the expected quantities were enormous. For these reasons, and perhaps because of the knowledge that uranium was potentially very toxic, a major effort was decided upon. I suspect the characterization "the most comprehensive experimental investigation of an industrial poison ever carried out by any group of scientific workers in such a short time" (Voegtlin and Hodge 1949) could well embrace all of toxicology, not just industrial poisons.

As indicated in the overview, the work on uranium differs markedly in outlook from that surrounding any other element or group in this compendium. Natural uranium is so weakly radioactive that its potential as a chemical poison far outweighs any possible radiation hazards, at least in terms of acute toxicity.

A true threshold below which no effect would occur was expected for uranium, as for most chemical poisons then known. Also, the usual sigmoid dose-response curve was assumed to hold (and was found). The only exceptions to the lack of radiation effect were the possible effects of the higher-specific-activity isotopes and uranium fuel enriched with these, and the possibility that long-term exposures to insoluble compounds, even of natural uranium, might, given long enough, pose a radiation hazard.

II. World War II

A. General Organization

The laboratory studies of uranium began almost immediately after the organization of the Medical Section of the Manhattan Project. They were so extensive and so intensive that they might be compared to a major military operation—a sort of “storming of the heights.” Two laboratories undertook the bulk of the work: the Project at the University of Rochester Medical School, Rochester, New York.

At Rochester, the work began by sealing off with guards a portion of the biochemistry department in the basic science section of the school, as well as constructing a “temporary” building across the street from the Medical Center attached to a building housing one of the early million-volt x-ray machines. Within a year, this building was extended with a one-story addition, which was deceiving in size. These facilities were able to house not only the laboratory work but a very sizeable animal facility for the development of the Rochester strain of the Wistar white rat. (Holding facilities for larger animals were in the earlier building.) Pictures of this facility as it was in World War II and as it now looks are shown in figures 2.1 and 2.2.

It is difficult to imagine that as many as 350 workers operated in that facility. While not all were devoted to the uranium work, as later chapters will describe, that effort was the largest single enterprise.

Dr. Harold C. Hodge directed the undertaking at Rochester with senior assistants brought in from the most disparate of backgrounds. (Their names will appear as we proceed in this and chapter 9.) Of course, tight security was clamped upon the operation, and the process of compartmentalization began as described by others dealing with the general history of the Manhattan Engineer District (e.g., Friedell 1981). Since the project was geographically closely integrated with the school, the imposition of security measures led to some friction, which was augmented by the fact that the pay-scale in the project was higher than in the rest of the school. There is a story (Neuman 1978) that the dean of the medical school^(a) decided one day to see what was going on in what was still part of his biochemistry department. Although he undoubtedly later on had full security clearance, he did not have the proper papers for entrance, and the guard refused to let him in. It is stated that the dean never again set foot in the project until after the war years.

The approach was very much a mass production format. There were working groups for hematology, pathology, and so forth of considerable size (figure 2.3). Work went on a three-shift basis, with individual workers in each group receiving material with only code numbers.

(a) Dr. George H. Whipple, Nobel Prize winner for his work on anemia.

FIGURE 2.1. Early view of the "temporary" buildings housing the MED work at the University of Rochester Medical Center. The one-story building at the right included the animal colony and most of the inhalation exposure chambers. Note that as many as 350 people worked in this facility, about half of them on the uranium work, on eight-hour shifts around the clock. (Courtesy of University of Rochester Medical Center Photographic Unit.)

FIGURE 2.2. Later picture of the University of Rochester facility that housed, in part, the Post-World-War-II uranium studies. A third story had been added to the central section. (Courtesy of University of Rochester Medical Center Photographic Unit.)

FIGURE 2.3. Group picture of Hematology Group, which worked largely on the MED uranium experiments at the University of Rochester. (Courtesy of the University of Rochester Medical Center Photographic Unit.)

The work at Chicago began at the Medical Research Institute of Michael Reese Hospital and was concentrated there, although some went later to Site "B," a former brewery fitted up for laboratory research. An outside view of this handsome facility is shown in figure 2.4. It was part of the Metallurgical Laboratory of the Manhattan Project and was really a side-show of the Plutonium Project. The work on uranium was under the direction of Albert Tannenbaum with special assistance from Samuel Schwartz and others listed in the references for this chapter. It was under the broad supervision of Robert S. Stone, Chief of the Health Section of the Metallurgical Laboratory.^(a)

Since the Chicago project was taken up with plutonium, fission products, and other important aspects of the broad effort, the uranium work was not as intensive or extensive as it was at Rochester. But it was a very significant contribution. It was concerned largely with injection and ingestion and with mechanisms, a fundamental area where it was well to have two laboratories at work. There were a few isolated studies elsewhere.

In addition to the intensive laboratory work, there was of course the need for industrial and field measurements and interpretations. The industrial control aspects will be considered in a separate section, and the complicated and very significant problems of uranium mining are taken up in chapter 3.

(a) The work at Michael Reese Hospital seems to have preceded by a few months that at Rochester, and Tannenbaum remained there almost exclusively. But the very earliest MED work on uranium, like so much else we will discuss in later chapters, seems to have involved tracer studies, in this case with ^{233}U , in the Berkeley laboratory of Joseph G. Hamilton (Hamilton 1948a,b,c).

FIGURE 2.4. An outside view of "Site B" of the Metallurgical Laboratory at Chicago. This was the delivery alley. The converted brewery held most of the animal work on fission products and transuranics and some of the uranium work. Most of the uranium work was done at the Michael Reese Hospital. No pictures were allowed of the inside of Site B because of security regulations. (Courtesy of Drs. Austin Brues and Miriam Finkel.)

B. The Initial Approach to the Toxicology

Despite the large amount of work with uranium already done, none of it really addressed the immediate needs of the Manhattan Project. What toxicological information was available involved levels far too high to guide even these early wartime efforts. As Hodge vividly describes in the foreword to the first volume accounting the war work in the National Nuclear Energy Series (NNES) (Voegtlin and Hodge 1949), the need was to know levels that would be without *serious sequelae*. Which of the numerous uranium compounds were more dangerous, and exactly how toxic was each? This meant initial experiments at levels that would produce effects in reasonably short periods followed by work at lower and lower levels and longer and longer exposure periods. It also meant the development of much more sensitive methods for measurement of low concentrations of natural uranium. It meant development of reasonably quantitative methods for inhalation exposure, and, if possible, some reliable and simple tests for damage produced by any exposure.

Some of the very early instrumentation and methodology were unbelievably crude by the standards of even a few years later. Dr. William F. Neuman at Rochester described to this author (Neuman 1978) how his assignment to develop an ultramicro analytical method for uranium got under way. Dr. Walter Bloor, who was chairman of the biochemistry department of the medical school and an analytical chemist, used an old colorimeter to fashion a spectrophotometer whose light path was conditioned by passing it through some amber glass

from broken beer bottles. The source was a headlamp from a Model T Ford operated from a six-volt storage battery. The receiver was a plain photocell connected to a wall galvanometer with a light path of about 35 ft.^(a) Yet, this was the beginning of a truly ultramicro method (see "The Fluorophotometric Determination of Uranium" by Bloor and Neuman 1949 and Neuman et al. 1948a).^(b)

Similar crude beginnings for the early inhalation studies are described by Rothstein (1978). There was little time for formality. The investigator, a carpenter, and a machinist might get together, discuss a general layout, and go ahead to build the needed equipment by trial and error. A useful exposure chamber unit was thus constructed, even though the first "dust feed" consisted of a large salt shaker being banged against a heavy metal base plate!

Despite the compartmentalization of thought and effort imposed by security restrictions, it appears that the Chicago and Rochester groups had enough high-level conferences to make decisions on the broad scope of each laboratory's work. It is not so clear how much information was exchanged on methodology. Since Chicago was to do only ingestion and injection for toxicology investigations, they were spared the onerous task of building inhalation exposure chambers and dust feeds. But they did need to measure uranium. Reference to methodology on uranium is scarce in the early MED literature from Chicago. But we do find citation of "Fluorophotometric Determination of Uranium" (Price, Ferretti, and Schwartz 1953) in one of the oldest of the report series. Whether this was developed independently of the Rochester effort is not clear; at least the same principles seem to have been utilized.

While these experimental studies were getting under way it was necessary to establish working rules for the workers already beginning the processing of uranium ores, and beginning operation of the many chemical steps of separation, and the fabrication of fuel elements. Since lead had been studied extensively and there was much experience both in animals and in exposed workers and members of the general population, and there were many apparent similarities between uranium and lead, an interim daily exposure level for uranium was devised by analogy to lead. This took care of the immediate industrial exposure criteria, and the laboratory work could get under way in earnest in parallel with the early process development.

C. The Initial Toxicology Results

The results of the uranium work on animals at Rochester and at Chicago have been documented in extenso in the volumes of the NNES (Voegtlin and Hodge

- (a) The wavering path of the galvanometer light spot in a building constructed on piles over quicksand and the agonizing slowness of this procedure are factors only those who have had to use such methods can appreciate.
- (b) As was the custom throughout the Manhattan Project, several methods were developed simultaneously since there was no time to wait for sequential developments. The result was frequently a variety of methods used for different levels of sensitivity, convenience, etc. The sensitivity of the fluorophotometric method was astonishing for a chemical (as contrasted to a radiochemical) method. The Chicago group gave their sensitivity as 0.001 μgm uranium (Ferretti and Schwartz 1946); the Rochester group gave 0.005 γ/g (Neuman et al. 1948a). Obviously, the car headlamp had been replaced by an ultraviolet light source, and many other changes were made before the fluorophotometric method achieved the sensitivity just given.

1949; Voegtlin and Hodge 1953; Tannenbaum 1951), in summary fashion by Yuile (1973), and by Durbin and Wrenn (1975).^(a)

The initial work involved primarily the rat at Rochester and the mouse at Chicago, but other species entered as the work progressed. Every conceivable route of entry was tried: parenteral injection (i.e., intravenous or intraperitoneal), feeding, application to the skin and to the eye, and inhalation. The first experiments were short-term, e.g., twenty-four-hour mortality, mortality in fourteen to twenty-one days, etc. But these were soon extended to thirty-day feeding tests involving dogs and rats, one-year feeding tests with dogs and rats, and inhalation exposures from acute ("pilot tests") to repeated exposures for up to one year.

The compounds studied were legion and included the gas uranyl hexafluoride (UF_6), UO_2F_2 , uranyl nitrate, UCl_4 , UF_4 , "high grade ore," UO_2 , UO_3 , UO_4 , $\text{Na}_2\text{U}_2\text{O}_7$, $(\text{NH}_4)_2\text{U}_2\text{O}_7$, and U_3O_8 . The highlights of the earlier toxicological findings are summarized below.^(b)

1. There is a wide range of transportability of the various uranium compounds. Perhaps the easiest way to illustrate this is to borrow a table (table 2.1) prepared by Scott (1973) and published in the volume edited by Hodge, Stannard, and Hursh (1973).

TABLE 2.1. Classification of Uranium Compounds According to Transportability^a

Highly Transportable	Moderately Transportable	Slightly Transportable
UF_6	UO_2^b	UO_2^b
UO_3^b	U_3O_8^b	U_3O_8^b
$\text{UO}_2(\text{NO}_3)_2$	UO_3^b	Uranium oxides
UF_4^b	UF_4^b	Uranium hydrides
Uranium sulfates	Uranium nitrates	Uranium carbides
Uranium carbonates		Salvage ash

^a Partially developed from data by Steckel and West (1966), and Task Group on Lung Dynamics (1966).

^b Subjecting a particular uranium compound to higher temperatures tends to decrease rate of transportability.

Source: Reset from Scott 1973; references included in the bibliography for this chapter. Reprinted with permission of Springer-Verlag, Heidelberg, copyright 1973.

(a) The reviews of Yuile and of Durbin and Wrenn include both the MED days and post-war work. The discussion by Durbin and Wrenn includes consideration also of unsolved problems and is very complete and authoritative. For the original data, the series of papers by Neuman and colleagues in 1948 and 1949, and the Voegtlin and Hodge volumes should be consulted.

(b) Although the citations are postwar, the basic phenomena described in this section were apparent in the war work, with some obvious exceptions.

2. The "soluble," i.e., transportable forms of natural uranium are deposited primarily in kidney and bone.^(a) They leave the kidney quickly and are excreted largely via urine. If the levels are above the threshold for kidney damage, effects localized almost entirely to the proximal convoluted tubule can result. Only at very high levels does the damage extend to other parts of the kidney. The glomerulus seems singularly immune under ordinary circumstances.
3. Recovery from kidney damage, unless severe, is relatively complete. The cells replacing the damaged epithelial cells are different from those damaged by the uranium and are much less sensitive to subsequent exposures to uranium. This leads to the well-documented phenomenon of development of tolerance to uranium.
4. The insoluble forms tend to remain at the site of entry. Since this is usually the lung, large deposits of compounds such as uranium dioxide can accumulate in lung and accessory structures.
5. Biochemical changes occur concomitantly. These will be considered in a separate section.
6. Bone retention is long relative to retention in soft tissues, and uranium seems to enter bone by partial exchange^(b) for calcium and enters loosely into the hydroxyapatite crystal (Neuman and Neuman 1958). It does not seek bone surfaces as do plutonium and the actinide elements. (Also, as later work showed, it does not penetrate the crystal lattice of hydroxyapatite. It remains only at the crystal surface in contrast to calcium and related small ions. See Durbin 1986.)
7. Soluble uranium compounds can pass through the skin and can enter the body through the eye if splashed thereon.
8. Differences in species susceptibility are large but are so variable among the compounds that no generalizations can be made. Nevertheless, Hodge developed a composite score for toxicity (Voegtlin and Hodge 1949), which is reproduced as figure 2.5.
9. Significant increases in sensitivity of the analytical methods were accomplished, even though by current standards the equipment itself would seem crude.

D. Biochemical Aspects

The people recruited for the more senior posts in the toxicology effort were far from technical hacks, as was sometimes implied. They were good scientists, and, as good scientists, they instinctively turned attention to mechanisms and explanations whenever the opportunity presented itself. Fortunately, those in the higher medical echelons of the MED knew that the more there was known about mechanisms the more chance there was for intelligent treatment and control. They did nothing overt to discourage these investigations so long as

(a) Despite the mass of pre-World-War-II work on uranium, standard pharmacology texts never mentioned the deposition of uranium in bone, only its deposition in and effects on kidney.

(b) In the earlier literature, a full ion exchange process between uranium and calcium was considered proven. Since it appeared later that the uranyl ions did not penetrate fully into the hydroxyapatite crystal, I have termed the process *partial exchange*.

TOXIC RESPONSE SCORE	DUST	LEVEL mg/U/M ³
4	UF ₆	13
5	UO ₂ F ₂ ; UCl ₄	>9, 11
5.5	UO ₂ (NO ₃) ₂	11
6.5	UO ₄	13
7	UO ₃	16
8	"HI-GRADE" ORE	20
9	Na ₂ U ₂ O ₇ ; UF ₄	15, 18
9.5	(NH ₄) ₂ U ₂ O ₇	12
11	UO ₂	19
15	U ₃ O ₈ *	15
16		

*The position of U₃O₈ is fixed with less certainty than the others because of less detailed study.

FIGURE 2.5. Relative toxicity of twelve uranium dusts on a scale of four to sixteen. The route of entrance was inhalation. (Redrawn from Voegtlin and Hodge 1949, p. 40.)

sight of the primary practical goal was not lost, even though they could not openly condone or encourage any deviation from the mission-oriented approach.^(a)

The chemistry of uranium and its compounds was worked out exhaustively in the MED years as well as later. A good idea of the depth and breadth of the chemical information developed can be seen in the postwar review by Gindler (1973). Against this background, much could have been done more quickly in the MED days. However, the biomedical workers had to find out for themselves, since most of the chemistry described later was in a classified status during the war.

1. Complexing

The known chemistry of uranium had already pointed to its strong tendency to form anionic complexes with many moieties. In the early results of the MED, it was determined that the most important of these were complexes with protein

(a) This is a generalization. There were instances of open conflict between the higher military echelons and the MED scientists, and a certain amount of mutual contempt developed. This drove the mechanistic work underground to a degree. The portion of the budget allowed to be devoted to nonprogrammatic work was only 20% in the second year (none specifically allocated in the first year) and only gradually increased to allow 50% for mechanistic work in later years.

and with bicarbonate. Complexing with protein was considered the basis for the toxic action of uranium in the kidney, i.e., combination with the protein of the cells lining the tubular epithelium. The complex with bicarbonate was critical, because a significant portion of the uranium in blood was complexed with bicarbonate and entered the kidney tubules as such. In the proximal convoluted tubule, the urine becomes more acid, and the complex with bicarbonate is dissociated, leaving the uranyl ion free to attach to protein of the tubular epithelial cells. In this way, a reasonable explanation for the relative anatomical localization of uranium damage in the kidney was possible.

Many of the workers both at Chicago and Rochester were sophisticated chemists. The complexing process and systems receive detailed treatment in the chapters by Neuman and Tishkoff (1953) and in less detail in one by Barron (1951). Regardless of direct application or lack of it to biologically prime processes, the solution chemistry of uranium received ample and sophisticated study. The results have been and will remain valid for a long time.

One simple conclusion is that normally uranium is carried in the +6 valence state when in solution in biological fluids.

2. Urinary Tests for Kidney Damage

Long before the MED work began, it was known that animals or humans with kidney damage excreted protein (albumin) in the urine. Later it was clear that certain enzymes, such as acid phosphatase, also appeared in urine.

Considerable effort was expended to find a really sensitive, and preferably easy-to-determine, excretory product that might signal the onset of kidney damage in uranium workers. The most promising among these was the excretion of the enzyme catalase in the urine. This was developed in detail at Rochester (Dounce, Roberts, and Wills 1949) and also at Chicago (Katz, Holt, and Schwartz 1946). It came apparently from the damaged cells of the tubules by either a change in permeability or cell breakdown and was in no way correlated with glomerular filtration rate. It was more specific than proteinuria, and the catalase activity of urine was easily determined.

All of the animal experiments pointed to the excretion of catalase as a very promising measure of threshold kidney damage. It was, therefore, a considerable disappointment when it was found and reported by the Chicago group that it did not work in man (Katz, Holt, and Schwartz 1946) at levels of uranium exposure anticipated in practice. Personnel from the Ames Research Laboratory (Iowa State University) showed no significant difference among twenty-six individuals chronically exposed to fairly large amounts of uranium and twenty-three control students. Nor was there any elevation of urinary catalase in Project personnel exposed to smaller amounts (Schwartz 1951a, p. 38; also Katz, Holt, and Schwartz 1946). It should be added, however, that from what we now know of the actual amounts of uranium entering the body in cases originally set down as "fairly large exposures," the problem may have been more one of underexposure than lack of sensitivity of the test in man. (These problems will be reviewed further in chapters 9 and 16.) Many other entities appear in the urine of animals exposed to uranium. These include coproporphyrin, various enzymes, protein, amino acids, etc. But none seemed to be really specific, and monitoring of man seems to have settled on albumin and cell debris, even though it appears that a careful monitoring of amino-acid excretion is really the best indicator (Rothstein 1978) or possibly a combination of three tests (Hodge 1953a in Voegtlin and Hodge 1953, p. 2391).

3. Metabolic and Cellular Effects

It was established early that uranium was a potent enzyme inhibitor. In the Chicago work, Barron (1951) at first assumed the effects were by inhibition of sulfhydryl enzymes—Barron was a strong proponent of this very popular notion for a large variety of drugs and toxic agents (Barron, Muntz, and Gasvoda 1948). The Rochester group could find no evidence that this was the mechanism (Dounce 1949). Despite the barrier of security, a moderately heated polemic ensued. But by the time the more complete papers were written (e.g., Singer et al. 1947) there was no contest. Indeed the evidence presented—no loss of -SH titer, lack of reversal by BAL (British anti-lewisite) or glutathione, and lack of correlation between sensitivity to UO_2^{++} and the presence of “essential” SH groups—eliminated any possibility that enzyme inhibition by uranium involved sulfhydryl group combination. The physical-chemical work at Rochester was pointing to quite a different mechanism anyway. Other metabolic studies were summarized by Berke et al. (1953).

Unfortunately, despite a very considerable amount of work, no close association between specific enzyme inhibition as measured in vitro and uranium's toxic effects could be drawn (Dounce and Lan 1949). However, a very exciting prospect developed out of work at both Rochester and Chicago using intact cells. This was followed up insofar as was feasible even during the war years. It led to an entirely new view of the functions of the cell membrane and formed the basis for several productive postwar scientific careers, indeed for the entire field of membrane biophysics.

Briefly, the story begins with the finding of extraordinary sensitivity to uranyl ion of glucose uptake by intact yeast cells (Muntz, Singer, and Barron 1947).^(a) Concentrations as low as 10^{-5} M of uranyl ion had marked effects. This was readily reversed by the addition of phosphate to the medium. Rothstein (1953) and his colleagues followed through with very detailed studies that proved that the action on intact cells was quite different from that in a maceration juice. (The Chicago group also demonstrated this.) *The uranyl ion did not pass through the cell membrane.* Thus, the uranium was complexing with entities in the cell surface, i.e., active groups of enzymes. It was exerting most of its effect on glucose uptake without even entering the interior of the cell! Thus, for the first time, the presence of enzymatic reactions vital to cell metabolism was demonstrated to reside in the cell surface or membrane. The details and ramifications of this work, begun as part of the MED practical work, came to full flower in the postwar years (more in chapter 21).

It remains somewhat an open question as to the extent to which these cell surface reactions account for the action of uranyl ion in the kidney tubule, but the importance of the findings to cell biology stands regardless.

Whole-animal biochemistry, i.e., clinical chemistry, was investigated in most of the studies. The results, described in the NNES monographs already cited, indicate that systemic uranium can interfere with normal carbohydrate metabolism of dogs and rats (Hodge 1953b). If enough uranium is given, organs other than kidney (e.g., liver) begin to show alterations of metabolism. Some alterations in porphyrin metabolism, not incontrovertibly associated with a direct action of uranium, turned up in the Chicago work (Schwartz 1951b). Most of the changes in clinical biochemistry could be referred to kidney lesions and disorders of kidney function at doses near the threshold level.

(a) A large variety of cell systems was studied in addition to yeast, but cannot be detailed here.

4. Bone

Uranium deposits primarily in kidney and bone. It leaves kidney and other soft tissues very rapidly. Thus, deposition in bone is the most important long-term storage mechanism for uranium introduced in soluble form. The detailed biochemistry of the processes involved, as studied during the MED days, is summarized by Neuman in many papers in the open literature and most easily studied in his chapter in the Voegtlin and Hodge monograph (Neuman 1953). The fact that it enters largely by ionic exchange processes and is a "volume seeker" in modern parlance was amply clear.

In addition to studies on whole animals to determine the role of factors such as age, diet, etc., a large effort went into in-vitro studies. These have become an integral part of today's background for the biochemistry of the heavy metals and cations in general in bone (Neuman and Neuman 1948, 1958; Neuman, Neuman, and Mulryan 1948; Neuman et al. 1948b; 1949a,b,c).

Somewhat akin to the work on cell surface enzymes, this wartime work on bone formed the basis for some other postwar careers and fields of activity.^(a)

Perhaps because of the weak radioactivity of natural uranium, perhaps because of the biochemical interests of most of the investigators, the possibility that uranium deposited in bone might be a source of cancer is never mentioned in the literature of those days. This stands in sharp contrast to the attention directed to carcinogenesis from the more highly radioactive bone seekers such as radium, plutonium, strontium, etc. There is no evidence that natural uranium has ever produced a bone tumor; nevertheless, the difference in viewpoint is interesting. It may well reflect the compartmentalization engendered by security as well as the different interests of the investigators.

E. Pathology

The gross and microscopic pathology of uranium poisoning was already well understood at the beginning of the MED days. Naturally, routine histopathology was done in most of the toxicity experiments, but the results served largely to "fine-tune" what was already known.

Perhaps the most efficient way to summarize is by quoting from Yuile's (1973) description of the animal studies:

Since the earliest animal experiments with uranium, there have been numerous descriptions of the morphological expression of its renal toxicity based on experiments on animals of various species, age and sex. Different uranium compounds have been given in widely different doses and by various routes as either single or repeated administrations. Despite these differences, remarkable similarities are noted between the numerous pathological descriptions and interpretations found in the literature. The changes, which share many features with poisoning by other heavy metals such as mercury, are not specifically diagnostic of the effect of uranium. There is, in general, an inverse relationship between the time of onset and severity of the renal lesions and dose in any given susceptible species.

The proximal convoluted tubules show the earliest change consisting of vacuolization and the accumulation of hyalin droplets and other cytoplasmic bodies. There is a lag period of from about 6 hours to several days in the appearance of these changes, depending on the dose, and ultimately, with administration of

(a) In combination with work on the radioactive alkali metals and the actinides, much of modern bone physiology and biochemistry got its start in these MED studies.

sufficient amounts of the material, cell necrosis is seen. The necrosis appears initially in the lower portion of the convoluted tubule. With lower doses it is spotty in distribution and following higher doses, may extend as wedge-shaped areas into the outer cortex toward the capsule. Casts, either hyalin or containing shed necrotic cells, are present in considerable numbers after the first few days at all levels of the tubular system. After 2 or 3 days, evidence of regeneration of the lining of the convoluted tubules becomes apparent, depending, to some extent, on the severity of the initial injury. In non-fatal cases, after about 2 to 3 weeks, the lining epithelium is completely reformed but the individual cells are morphologically and functionally abnormal for considerably longer periods of time. Regenerating epithelium takes several forms. Nuclei tend to be larger and darker than normal, with mitotic figures being frequently seen in the early stages. Cytoplasm is basophilic and often flattened. As regeneration continues and the kidney becomes more and more normal in appearance following sublethal doses of uranium compounds, subtle changes are seen for a considerable period of time so that it is difficult to distinguish between regenerated cells and cells which have been "activated" in some fashion. (Yuile 1973, pp. 186-187)

III. Postwar Animal Studies

At the conclusion of World War II and the disbanding of the Manhattan District, many projects were in midstream and required much more work to realize a return on the investment of the MED efforts. This was not true for natural uranium. The prodigious efforts of the war years could be regarded as having accomplished most of their goals. The chief residual problems concerned the metabolism and possible radiation effects associated with very long-term exposure to insoluble uranium compounds, some miscellaneous extensions on specific problems, and the acquisition of more and better data on man. This section takes up the postwar animal studies with direct connections to the earlier work.

A. The Rochester Inhalation Experiment

By far the most extensive postwar experiment with animals was a long-term inhalation project at Rochester. The purpose was both the determination of retention and "metabolism" and potential development of long-term effects in the lung and accessory respiratory structures. By using insoluble UO_2 dust, the potential for chemical effects on the kidney was minimized. An entirely new exposure chamber set-up was designed and built. A picture of the installation is given in figure 2.6. Exposure started in 1955 under the auspices of the University of Rochester Atomic Energy Project, supported by the Atomic Energy Commission (AEC). Rats, monkeys, and dogs were exposed for six hours per day, five days per week to an aerosol containing about 5 mg/m^3 with mass median diameter of about $1 \mu\text{m}$ for a maximum period of five years in the dogs and monkeys. There were serial sacrifices to determine distribution and retention and clinical determination of the general health of the animals. Despite the accumulation of large quantities of UO_2 dust in lung and tracheobronchial lymph nodes, there was little transfer to kidney or other tissues and no evidence of kidney damage or hematologic changes. The results to the end of the five-year exposure period were described by Leach et al. (1970). Except for fibrotic changes in the lymph nodes of monkeys and dogs suggestive of radiation injury and some lung changes in monkeys, there was surprisingly little obvious effect in the five years of exposure.

FIGURE 2.6. Photograph of one bank of the inhalation chambers used for the large postwar inhalation experiment at Rochester. The design accomplished extremely uniform distribution patterns inside the chamber. (From Leach et al. 1959. Reprinted with permission of *American Industrial Hygiene Association Journal*, Akron, Ohio.)

Fortunately, the experimenters had the vision to hold groups of animals for postexposure study. Some were used to determine pulmonary clearance of the accumulated deposit. It was much slower than clearance after a single exposure. Other animals were held for as long as six years postexposure to look for long-term pathology. The patience of these investigators, especially after the demands of the five-year exposure routine, must be admired, as must the vision of the AEC in providing continued financial support. There is no substitute for actual measurement of long-term distributions and effects.

The patience and effort put into this experiment paid off. Pulmonary fibrosis, comparable to that seen after plutonium inhalation, noted in the lungs of monkeys even before the end of the five-year exposure period, developed markedly during the postexposure years. The lymph nodes, which were literally loaded with uranium, also showed combinations of fibrosis and necrosis similar to those seen with $^{238}\text{PuO}_2$ and $^{239}\text{PuO}_2$. But the most interesting finding was the incidence of neoplasms, metaplasia, etc. in the dogs kept for the full term. Although the incidence was not high, the type of lesion seen essentially never occurs spontaneously in the dog. The radiation dose was calculated as over 10,000 rad in the lymph nodes, considerably less in the lungs, but still hardly minuscule. The monkeys, while showing marked fibrotic changes, did not show frank neoplasia.

These results show that it is possible to produce cancer in at least one animal species with natural uranium if exposures are long enough and accumulations

large enough. In a sense, however, they demonstrate how far above the normal "tolerance" level the tissue contents must be to produce neoplasia. Also, the compound must be very insoluble and thus retained for long periods (Morrow, Gibb, and Leach 1966). Contrast for example the rapid clearance from the lung of the closely related uranium trioxide (UO_3) reported by Morrow, Gibb, and Beiter (1972).

Details of the final results of this work can be found in Leach et al. (1973) and are summarized in the fine chapter by Yuile (1973).

B. The Oak Ridge and Related Experiments Using Animals

The Health Physics Division at Oak Ridge National Laboratory (ORNL) has engaged in few animal experiments (except those concerned with the environment). Their interests have been elsewhere. The ORNL Biology Division had more than enough animal work under way for any one installation. But the Health Physics Division did have the Internal Dose Center, and certain specific questions on the distribution and excretion of uranium seemed to require direct determination in animals. Under the initial direction of Mary Jane Cook and later under Bernard Fish and still later in collaboration with Robert Bernard, some ^{235}U studies were undertaken. These were described by Fish (1958, 1961), Fish and Bernard (1961), and by Fish and colleagues in other ORNL reports (e.g., Fish, Payne, and Thompson 1960). The work involved rats primarily but also a few dogs, using both ingestion and inhalation routes. The data were useful primarily for checking out some of the biologic constants being used in the Oak Ridge Information Center for Internal Exposure (Ford 1964).

C. Other Postwar Animal Experiments

Several investigators used the postwar availability of the higher-specific-activity isotopes of uranium to probe into microdistribution and the possibility of a mass effect. The technique of autoradiography was applied in conjunction with conventional analytical methods. These essentially confirmed by more sophisticated methods what had been established in the MED work (Kisielewski et al. 1952; Jones 1966; Walinder, Hammarström, and Billaudelle 1967; Walinder, Fries, and Billaudelle 1967). It is interesting to note that the last papers come from Sweden. Tannenbaum (1951) gives a reference to a British report on uranium toxicology, published in 1943. By and large, however, biological work abroad with uranium was sparse during the period of greatest activity in the United States.

IV. Data On Man

A. Occupational Exposure

Although the uranium industry had both the largest number of potentially exposed persons and some of the worst conditions of exposure during the war years, the incidence of obvious damage from routine exposures is almost nil. Only after accidental releases of moderately large amounts were frank effects seen. There was an extensive bioassay program at all the uranium processing facilities. Excretion of uranium in the urine was regularly measured, and signs of kidney damage such as the presence of cellular debris or elevation of one or more of constituents such as amino acids, nonprotein nitrogen, albumin, catalase, etc., were regularly checked on. The incidence of these indicators of

damage was relatively low. As a result, it began to be concluded that natural uranium was less toxic to humans than the animal data predicted.

This conclusion, even after these many years, is not a certain one. As brought to light at an AEC symposium on uranium in 1958 (AEC 1959) and expanded upon by Eisenbud (1959), the lung burdens in personnel exposed to insoluble uranium were far below what would be predicted from the measurements of exposure (i.e., the amounts in air). Such information came from post-mortem autopsy data (Eisenbud and Quigley 1956; Donoghue et al. 1972; and summarized by Hursh and Spoor 1973). Also, less retention of soluble uranium than expected was reported for autopsy specimens from an employee who had worked with uranium hexafluoride and died of a coronary thrombosis (Butterworth and McLean 1955).^(a) Further data are given by Quigley, Heatherton, and Ziegler (1959) and Marks (1975).

Unfortunately, and despite the large number of potential cases and situations available for examination, the presence of a truly significant difference in the toxicity of uranium in man compared to several animal species studied cannot be separated from difficulties in the characterization of the exposures. The air sampling methods used in the days of "high" exposures were not very selective as to particle size. Thus, a significant portion of the apparent exposure may have been to nonrespirable particles. And now that the sampling operations are fully capable of detailed particle-size analyses, the operations have become so clean that exposures sufficient to produce toxic effects are limited to the rare accidental releases! The most recent symposium on uranium has highlighted this point (see Eisenbud 1975).

It could be imagined that retrospective analyses and some sophisticated epidemiology applied to the wartime plants and personnel would have solved these problems. But as Eisenbud vividly pointed out at the ERDA symposium, the effort has been weak indeed. He adheres to the view that uranium is clearly less toxic in man than the animal studies indicated. But he also highlighted the frustrations of trying to prove this by pointing out that the literature from animal studies amounted to several thousand pages between 1958 and 1975, but the epidemiologic literature at the time of his paper did not exceed twenty-five pages. Also, the last epidemiologic data to appear seem to be more than twenty years old.^(b)

At long last, a Uranium Registry was established officially in 1978 (Marks 1979). This will operate in much the same fashion as the older Transuranium Registry (more in chapter 16). It remains to be seen if this effort can salvage some of the opportunities missed to learn the true health status of the many hundreds of workers who handled uranium in the production chain^(c) from 1943 to 1954. Why it took so long for the message to get through will always remain a puzzle.^(d)

(a) See also later review by Butterworth (1959).

(b) This author's experience in trying to track down the records of uranium workers for a National Council on Radiation Protection (NCRP) committee was equally frustrating until recently.

(c) This does not include the uranium miners, which are a separate group with a very different problem.

(d) In the early 1980s, epidemiologic studies of populations such as those that worked at the Tennessee Eastman Plant in Oak Ridge were mounted, and early reports have appeared. So far, no abnormal incidence of the potential effects has come to light (more in chapter 16).

There were, of course, a few accidental overexposures which have been reported. Howland reported a wartime accident in which UF_6 , UF_2F_2 , and HF were involved. There were two fatalities and three serious injuries (Howland 1949). But the problem was largely the corrosive HF and F,^(a) and only minimally the uranium.^(b) Exposures more directly relatable to uranium were presented by Fish (1958, 1961), Schultz (1966), Saxby et al. (1964), and Ronen (1969). All of these are considered in some detail by Hursh and Spoor (1973), and, in general, the only conflicts with animal data were occasional long retention times in the body or in lungs and, with the latter, considerable excretion via feces.

There were also instances where workers handling the higher-specific-activity isotopes via enriched uranium showed above-tolerance urinary excretion levels.

B. Planned Administrations

1. Intravenous Injection

a. Rochester Study

As part of the MED effort at Rochester, Bassett and coworkers (1948) carried out a study on hospital patients. Six subjects were selected and placed in the metabolic ward. They were in sufficiently good health that the results seemed unlikely to be vitiated by their disease. Yet, they were clearly in a position to benefit from continued hospitalization. The aim was primarily to check the metabolism of uranium (i.e., distribution and excretion) and not effects except incidentally. The subjects received uranyl nitrate, a soluble salt, enriched with ^{234}U and ^{235}U to make measurements easier with the small quantities involved. But to be doubly sure that the levels were below the threshold for damage, renal function tests were applied in depth to some, in part to all. The doses ranged from 6 μg to 70 $\mu\text{g}/\text{kg}$ of body weight.

The metabolic data indicated rapid urinary excretion and no sharp conflicts with the animal data. Only at the 70- $\mu\text{g}/\text{kg}$ level was there a slight rise in urinary catalase and protein suggesting that threshold kidney damage had occurred. The effect was transient. This experiment has been described and interpreted in depth by Hursh and Spoor (1973) and will be considered again in chapter 16.

In the early postwar years, Terepka, Toribara, and Neuman (1965) wished to check in man the evidence obtained earlier in animal work—that the handling of uranium by bone might be an indicator of skeletal metabolic disorders. Three controls and seven patients with bone disorders received 30 μg of soluble (hexavalent) uranium. Retention was regarded as a function of the relative amount of exchangeable bone, especially when compared with calcium. The results helped distinguish the contributions of bone accretion and bone resorption to the disease at hand since, of course, the uranium enters bone in exchange for calcium.

b. The Boston-Oak Ridge Intravenous Injections

The background for this project lies in the hope of using neutrons for radiation therapy. Some trials had been carried out by Dr. Lee Farr and associates at the

(a) Very recently, the information from these cases has been re-examined and a possible long-term role of uranium suggested. (Kathren, personal communication 1985).

(b) The production of large quantities of compounds in which uranium was combined with fluorine led to a detailed study of fluorine and fluoride toxicity in the Rochester MED work. I have chosen to omit this as not bearing directly on internal emitter toxicology.

Medical Division, Brookhaven National Laboratory in which boron salts were given to patients with advanced brain tumors, and the head area was then exposed to a neutron beam from the old Brookhaven reactor or "pile." If there were sufficient localization of the boron in tumor tissue, the neutron beam might produce specific therapy within the tumor by the n, α reaction.^(a) The results were disappointing.

Dr. William H. Sweet at MGH conceived a different approach. If partially enriched uranium would concentrate in tumor tissue, the neutron beam might produce highly specific and localized damage by the production of fission fragments. Meanwhile, the Health Physics Division at Oak Ridge National Laboratory was interested in better data on the metabolism of hexavalent uranium in man. There ensued a collaborative effort between Oak Ridge and the Department of Neurosurgery at the Massachusetts General Hospital and the Veterans Administration Hospital in Boston, whose justification was the possible benefit of the neutron capture therapy to the patients.

Eight patients who were in terminal phases of severe central nervous system disease were studied. Six were injected with a uranyl nitrate solution enriched in ^{234}U and ^{235}U , two were injected with tetravalent uranium as UCl_4 . The doses varied from 0.097 to 0.28 mg uranium per kilogram and thus were at the upper end of the scale, considerably higher than in the wartime study at Rochester. (Enough uranium had to be present to give some hope for the neutron capture therapy.)

There was not enough concentration of the uranium in tumor tissue to encourage further forays in the therapeutic realm. But a very complete effort was made to find out as much as possible about the metabolism of uranium in these patients. The results are given in detail by Luessenhop et al. (1958), and in somewhat abbreviated form by Struxness et al. (1956) at the First International Conference on the Peaceful Uses of Atomic Energy. They also are analyzed and compared with other studies by Hursh and Spoor (1973). The metabolism data were considered in the context of maximum permissible concentrations by Bernard (1958).

In general, the experiment agrees with the other intravenous studies and with the animal data, particularly those from the laboratory rat. The parlous clinical condition of the Boston patients would have raised questions of validity of the results had they differed markedly, so it is fortunate they are in general agreement. Since several of the Boston patients died within days or weeks after the injection, it was possible to get autopsy material while there was still enough uranium present to be measured. This represents one of the few instances in man where tissue contents could be measured after a known dose in contrast to the great uncertainties of the exposure in the usual occupational situation as detailed in a previous section. This may be the most significant contribution of this rather heroic experiment. The data again indicate that the major conclusions of the animal work apply to humans, at least when the uranium is received by intravenous injection and one considers primarily distribution and excretion.

2. Other Planned Administrations

The administration of uranium as a therapeutic agent in the nineteenth and early twentieth centuries was usually oral. These uses are summarized by Hodge

(a) Boron has a high cross section for neutron capture and could theoretically provide a latent source of radiation in situ. (See chapter 20.)

(1973) and by Hursh and Spoor (1973). Surprisingly large doses seemed to be tolerated in some individuals. Yet, when Butterworth (1955) gave a dose lower than many of these to a volunteer subject, there was a violent gastrointestinal disturbance. It was speculated that the difference may lie in the dosage regimen since the early patients received several doses in ascending size and may have developed tolerance to it, or it may have been a case of high sensitivity.^(a)

Hursh et al. (1969) conducted an oral absorption study on four hospital patients using uranyl nitrate hexahydrate at 10.8 mg uranium dose. They measured urinary and fecal excretion and used the data in retrospect to interpret the reports from the early therapeutic administrations. Also, the low absorption from the gut found in the animal work was confirmed in man, although the figure was not as low as the then-current recommendations of ICRP and NCRP (see chapters 9 and 16).

Harris (1961) did a single experiment involving inhalation of uranium compounds by man. There were twelve periods of inhalation of UO_3 and five periods, all short, of inhalation of UF_4 . The purpose of the experiment was to check on the findings in industry already alluded to that showed a baffling lack of effects after exposures, which were presumably high enough to cause frank damage. This was a complicated and potentially very useful experiment. Unfortunately, the results were equivocal because of discrepancies in the balance sheet for uranium. The author was not able to repeat the work with other subjects. Hence, for direct measurement of metabolism and tissue burdens with known doses administered to man, we have no data for the inhalation route of entry. This is unfortunate in view of the importance of the inhalation route.

3. Commentary on Planned Administrations in Man

These experiments yielded enough information to support the view that the way man handles uranium and his reactions to it are not widely different from the predictions of the animal experiments. They are a unique resource in many respects. They were done when the use of hospital patients giving "informed consent" and of volunteer subjects, including frequently the investigator himself, was easier to arrange. Although there is no evidence that these administrations were in any way harmful or ill-considered at the time, it is difficult to imagine a present-day "human use" committee approving them. It is, thus, doubtful if we will ever have more of the same kind of information. We must, therefore, be content with data from normal industrial uses or the rare accidental overexposure. It may be fortunate that the current hysteria regarding any kind of radiation exposure would assure that ample information would be gathered from any such incidents. But barring these, and they are not going to be numerous, we will need to use what we have and whatever the new epidemiologic studies can garner from the depths of the past.

V. The Higher-Specific-Activity Isotopes and Enriched Uranium

In sharp contrast to the massive attack on the toxicology and all other aspects of natural uranium, only a token biomedical effort was made during the MED days to study the effects^(b) of ^{232}U , ^{233}U , ^{234}U , ^{235}U , and natural uranium at various

(a) Development of tolerance to uranium is a well-established phenomenon. It was shown in the MED work and described in detail in NNES volumes (Voegtlin and Hodge 1949, 1953).

(b) Use of, for example, ^{233}U as a tracer was much more common.

degrees of enrichment with ^{235}U and accompanying isotopes. It seems to be impossible to find a written statement as to why this was so. One can only surmise that the parallel studies of other alpha emitters, particularly plutonium and, to a lesser extent, radium and polonium, going on in the MED laboratories were considered directly applicable to possible radiation effects from the alpha-emitting uranium isotopes of higher specific activity. There was one study in the postwar period—probably initiated late in the war—that stands out as a classic. It will be taken up presently. Nevertheless, particularly in view of current interests in uranium-based rather than plutonium-based fuel cycles, the lack of attention to this subject left a significant gap in our knowledge for many years.

There was no lack of calculations for allowable concentrations of the various uranium isotopes based on radioactivity. For all but natural uranium, these were done basically by calculation of alpha dose or by empirical comparison with ^{226}Ra . An important problem was the determination of that point in the enrichment process where potential radiation dose instead of potential chemical toxicity becomes controlling. As a rule of thumb, the transition point was taken as 5% to 8% by weight ^{235}U (Ford 1964). Spoor and Hursh (1973) examine this problem in depth. They show that using specific alpha activity, and assuming that the proportion of ^{234}U to ^{235}U remains constant in the course of enrichment, the critical organ changes from kidney to bone (and by definition from chemical to radiation effects) at about 16% enrichment. If an alternative assumption is made, i.e., the isotope proportions are those that would result from the diffusion of uranium hexafluoride according to the ideal gas laws, the shift comes at about 8.5% enrichment. The rule-of-thumb figures probably represent a conservative interpretation from these.

There was some interest during the MED days as to whether or not ^{233}U was metabolized like ^{238}U . Tannenbaum (1945) reported that it was, and his paper was expanded and reproduced as paper 7 in the Tannenbaum book (1951). This finding lent support to the widespread use of the shorter-lived isotopes, especially ^{233}U , as a tracer for natural uranium. Quite small amounts could be detected by virtue of the great sensitivity of radioisotope detection and measurement.

Except for a very small experiment at Rochester on effects of ^{233}U on bone resorptive processes (Voegtlin and Hodge 1953, p. 2401), effects studies seem to have been limited to those at the Argonne National Laboratory of the toxicity of several alpha emitters and beta-gamma emitters relative to ^{226}Ra . The results first appear as a project report by Brues (1951) and in detail by Miriam Finkel in the open literature (1953, 1956). The effects reported were development of bone tumors and average survival time in CF1 mice. Uranium-233 was more effective on the basis of microcuries/kilogram administered dose than ^{226}Ra but considerably less effective than ^{239}Pu . When the effectiveness ratio is calculated on the basis of radiation dose, it is more nearly equal between ^{233}U and ^{226}Ra . But the many assumptions necessary for such calculations led Dr. Finkel to hold steadfastly to administered dose as the most valid criterion—in the tradition of classical toxicology.^(a)

(a) As described in chapter 1, a later, better radium experiment was conducted by Finkel and published in 1969 (Finkel, Biskis, and Jinkins 1969). While the comparison is not direct (i.e., in the same experiment) as it was in the earlier work, use of the data for ^{226}Ra from this later experiment makes it and ^{233}U appear even more similar in effectiveness.

It is to be regretted that the extremely important comparison of bone seekers, which was followed up by the large experiment on dogs at the University of Utah (to be discussed in later chapters), was not repeated for ^{233}U or any of the other pertinent uranium isotopes. Nevertheless, the Finkel experiment was well conducted; the data have been re-examined from the original protocols by Durbin, Wrenn, and Stannard (1975), and the conclusion that ^{233}U is less effective than ^{239}Pu seems established fully.

In the 1980s, the results of a program at Pacific Northwest Laboratory^(a) conducted by John Ballou have begun to appear. This considers all members of the ^{232}U decay series and some of the higher-specific-activity uranium isotopes. As with many such new enterprises, it was necessary to sort out the in-vivo relationships of parents and daughters in the decay series. This was described very recently at the thirtieth annual meeting of the Health Physics Society (Ballou and Case 1985). Other descriptions have appeared in PNL annual reports (e.g., Ballou 1985, which considers the results of inhaled ^{233}U - ^{232}U intake and oxide fuels and ^{231}Pa). This work should go far to fill the gap in our knowledge of behavior and effects of isotopes of uranium other than ^{238}U , especially those in the thorium fuel cycle left by the inactivity since the publication of Finkel's mouse experiments.

VI. Postscript

The story told in the above sections became almost dogma. Indeed, it was, when this chapter was first written.^(b) Little new work was done with uranium for many years. After all, was it not the most thoroughly investigated of the heavy metal toxins? Also, conditions in the plants improved greatly so that exposures declined markedly, and gradually the number of employees decreased. Only at Rochester was there some lingering experimental work. In the last decade, beginning with the symposium sponsored by ERDA in 1975, and especially in the last five years, there has been a resurgence of interest in uranium and new biomedical work. Some of it is described in chapter 15 and later. We will consider two aspects here.

The rudimentary metabolic models for uranium possible from the earlier work described in this chapter have been greatly expanded and improved. This was brought about partly by the needs for setting drinking water standards, but was far from limited thereto. The New York University (NYU) group began the modeling effort, particularly M. E. Wrenn and his graduate students. It continued at the University of Utah when Wrenn moved there. He was joined early by P. W. Durbin, at the University of California, Berkeley, who had begun work independently on a uranium metabolic model, partly to meet the needs of an NCRP committee, and partly via a long-standing interest in metabolic models. The resulting publications show the evolution from simple to complex and how important the right model can be to standard setting and to understanding what is going on in the body (Durbin and Wrenn 1975; Wrenn, Lo Sasso, and Durbin 1977; Roswell and Wrenn 1980; Wrenn et al. 1985; Durbin 1986).

The last named reference is a finely crafted summary of the entire history of uranium modeling, which Durbin presented in August 1984 at a workshop on

(a) Operated at Hanford for the U.S. Department of Energy by Battelle Memorial Institute. This institution is variously referred to here as Pacific Northwest Laboratory (PNL); Battelle, Pacific Northwest Laboratories; Battelle; and Battelle-Northwest (BNW).

(b) This was the first chapter written and had the earliest cutoff date (see preface).

uranium held in Richland, Washington. The proceedings of this workshop were published in 1986. Wierm was on the same program and presented details of the modeling he and Durbin had been engaged with as well as some other aspects of uranium metabolism and standards.

Meanwhile, back at Rochester, where it all started and where it never stopped completely, Paul Morrow set about answering some questions posed by a contract with the Nuclear Regulatory Commission (NRC). His results indicated greater chemical toxicity in the dog than the work quoted in earlier sections of this chapter and taken up in chapters 16 and 21. Indeed, his major report to the NRC suggested that the bench-mark threshold value for damage from uranium in the kidney ($3 \mu\text{g/g}$) might be too high (Morrow et al. 1982). He and his group applied a battery of much more sophisticated tests for kidney damage than was available in the days concentrated upon in this chapter. They found evidence for damage at blood or urine levels expected to be associated with $3 \mu\text{g/g}$ kidney. Furthermore, they showed that kidney damage was not as strictly limited to the proximal tubule as the earlier work showed. Finally, they addressed the phenomenon of tolerance. While the phenomenon was definite, their work indicated that it is much more complex than described earlier. There are different degrees of tolerance and different time courses in different organs and under different regimes.

Morrow was also present at the uranium workshop in August 1984 mentioned above. His paper provides an excellent review of how work in the recent past and ongoing is showing the degree to which we may have oversimplified the phenomena of uranium toxicology, both chemical and radiation (Morrow 1986). It is far from a closed book!

Such is the nature of biomedical research. Nothing was basically wrong with the picture described earlier; it has, however, been sharpened and refined, and this will probably continue to occur.

VII. Summary and Commentary

Biological effects of natural uranium were described in the 1820s. By 1860, it was being used therapeutically in homeopathic medicine for the treatment of diabetes. It was also used experimentally for the production of kidney changes resembling clinical nephritis. However, the true therapeutic benefits of uranium, unlike radium, were small compared to its potential for untoward health effects.

Even after it was demonstrated that uranium is radioactive, the bulk of the biomedical research focused on its action as a chemical toxin to the kidney. The effects of the radioactivity were considered less important because of the very low specific activity of natural uranium.

Despite a considerable backlog of research from the mid-1880s into the 1930s, the needs of the World War-II development of atomic energy were not met, primarily because the earlier work involved soluble compounds, while the expected compounds in the new enterprise were, many of them, quite insoluble. When the decision was made to proceed with the nuclear fission bomb project, it was realized that a large number of workers would be involved at the various steps. A major effort was put into making the workplaces safe by both application of safety measures and what has been characterized as "the most comprehensive experimental investigation of an industrial poison ever carried

out by any group of scientific workers in such a short time" (Voegtlin and Hodge 1949).

Two centers were responsible for most of the work on uranium during the Manhattan Engineer District days. These were the MED project at the University of Rochester Medical School, Rochester, New York, and a segment of the Metallurgical Laboratory at the University of Chicago, primarily the Michael Reese Hospital. Pioneer work was done at the Crocker Laboratory, University of California at Berkeley. In the postwar period, the Atomic Energy Project at Rochester mounted a long-term inhalation study, the Argonne National Laboratory at Chicago carried a few important residual problems to completion, and Oak Ridge National Laboratory joined for some studies. There were also scattered special studies at other laboratories, but, with these exceptions, work on uranium was much less emphasized in the post-World-War-II period than it had been during the MED days. This contrasts sharply with most other phases of the radionuclide research that were carried forward and amplified along lines very similar to the war work.

The work made it clear that, while uranium is a specific kidney poison, its primary storage depot in the body is bone, except for inhaled insoluble compounds, where the major storage depot can be lung. The solution chemistry was worked out in detail, biochemical aspects were very completely characterized, and at least two major lines of postwar investigation grew directly out of the uranium work. These were the chemistry and biochemistry of bone, which were shared with the earlier and continuing work on radium; and cell surface enzymes, whose discovery and characterization came directly from attempts to understand how uranium produced its effects on cells.

On the whole, the work has stood the test of time very well. Only one major area seems to have been neglected: effects of the higher-specific-activity isotopes and enriched uranium. While the work that was done has been very useful and informative, present interest in new fuel cycles makes the relative paucity, until very recently, of data on effects of ^{233}U , ^{234}U , and ^{235}U especially noticeable. On the other hand, the higher-specific-activity isotopes have been very useful as tracers in biochemical and pathological investigations.

An important area for future work is epidemiologic study of the large populations of uranium workers. At long last, this has begun and deserves attention and support in the future. After all, uranium workers were by far the largest population exposed occupationally in the MED and early postwar years. Fortunately, a retrospective study of the workers at the Tennessee Eastman Plant, operated in Oak Ridge during the MED days, has been undertaken by a group at Oak Ridge Associated Universities. This is fortunate because this operation seems most likely to have air concentration data, etc., that can be used now. It is anticipated that the publications will be appearing soon.

Not covered in this chapter, except for one experiment, is the large effort devoted to inhalation studies at Rochester, especially during World War II. These are reserved for chapter 9.

As with radium, there has been considerable interest in the concentrations of uranium in environmental media: water from various natural sources, air and water from natural sources, and manmade sources such as uranium mill tailings. Wide ranges of concentration have been found to occur naturally. There is, however, even less chance of demonstrating any biomedical effects in the populations concerned, except in the uranium miners, and theirs is not a uranium problem, as we will see in chapter 3.

Recently there has been much movement toward regulating, at very low levels, the amount of uranium in drinking water. Despite all of the research completed, there seems still to be debate about whether the chemical toxicity or potential long-term radiation effects should control the choice of limiting concentration (more in later chapters).

Capsule Chronology

- 1400 et seq.** Mysterious malady kills miners at early age in mountains around Schneeberg (Saxony) and Joachimsthal (Jachymov) in the Sudetenland, now Czechoslovakia. Called mountain sickness. Known throughout the following centuries.

Most of eighteenth and nineteenth centuries—therapeutic spas booming.

- 1879** Identification of the malady in Schneeberg mines as lung cancer. Thought to be lymphosarcomata. Causation murky.
- 1904** Radon and daughters identified as part of the uranium series. Work with animals begins, especially in Russia and France.
- 1913** Determined that the lung cancers are mostly bronchogenic carcinoma.
- 1920–1930s** Much use of radon generators in hospitals for preparation of radon seeds.
- 1921** Suggestion that radium and radium emanation might be causative agent for cancer in miners taken seriously, but not proven.
- 1924** Measurements of mine air begin. Correlations made between high radon areas and areas of high cancer incidence in the mines. Possibility that airborne radon might be causative agent embraced by Ludewig and Lorensen.
- 1926** Government of Czechoslovakia finally agrees the malady at Joachimsthal (Jachymov) mines is lung cancer. Followed by detailed scientific reports in early 1930s.
“Emanatorium” in use at Copenhagen.
- 1929–1930** Fifty percent of miners dying at Joachimsthal have carcinoma of lung.
- 1932** Lung cancer in miners of Germany and Czechoslovakia designated a compensable occupational disease. This greatly facilitated follow-up.
- 1935** Findeisen indicates nearly all uncombined atoms inhaled will deposit on bronchial epithelium.
Lung modeling begins in earnest.
- 1939–1940** Animal toxicology shows generalized inflammation, hyperemia, etc. from radon, but no lung cancers.
- 1941** First standard for radon promulgated (10^{-11} Ci/l). Evans and Goodman, National Bureau of Standards report.

WORLD-WAR-II YEARS

A relatively quiet period because of other war activities. Animal work by Lorenz at National Cancer Institute. Calculated radiation doses from radon considered too small to account for effects.

Radon measured in storage areas for uranium ore. Concerns develop over radon from uranium mill tailings.

Mitchell (1945) relates magnitude of calculated radiation dose to bronchi of miners to incidence of carcinoma. Other calculations made by Evans in 1950.

- 1950s** Great expansion of uranium mining in the United States.
Concern voiced for health of miners.
Requests made to U.S. Public Health Service for assistance in evaluating mines. PHS^(a) makes recommendations to states.
Problems of dosimetry emphasized.
- 1950-1951** Epidemiologic studies begin in Colorado Plateau area, both mines and mills. Also medical examinations begin, but funding very inadequate.
- 1951** Surveys of mines start. Holaday, Ayer, et al.
Bale's "memo to the files" pointing out greater importance of preformed daughters compared to those formed in vivo. Similar idea found in Ph.D. thesis by J. Harley (1952), published in 1953.
- 1951 and 1954** K. Z. Morgan suggests lowering allowable exposure level for radon.
- 1952** AEC New York Office lends equipment and assistance (Harley, Eisenbud), but AEC not taking direct responsibility.
Control measures by ventilation of mines recommended.
- 1953** Utah surveys all operating mines for radon daughters.
- 1953 et seq.** Extensive animal work at Rochester to analyze role of preformed daughters (Shapiro and Bale).
Animal work at Naval Radiological Defense Laboratory (Cohn).
- Mid-1950 through 1960s** Rochester work with animals. Acute LD₅₀ for radon similar to that for x rays (Morken).
Red cell count never fully recovers after acute radon exposure (Morken and Scott).
Precancerous changes seen in lungs, but no tumors (Scott).
- 1954** Epidemiology team on the Colorado Plateau becomes a discrete entity. AEC office at Grand Junction helps.
- 1954-1965** Uranium mining begins and ends in Canada.
- 1955** Chamberlain and Dyson propose major part of dose to trachea and large bronchi is from preformed RaA.
Seven States Uranium Mining Conference. Need for better dosimetric unit emphasized. Idea of "Working Level" (WL) born. Tending toward 10⁻¹⁰ c/l.
- 1956** Tsivoglou method used widely for evaluating inhalation hazard by measuring individual atmospheric contents of each daughter.
Bureau of the Budget discourages use of federal funds in the uranium mines study.
- 1956 et seq.** Working levels measured in thermal galleries of therapeutic spas.
- 1957** Working level defined in a PHS document and gradually adopted by all concerned.
Extensive medical survey. Increase in lung cancer incidence in miners of Colorado Plateau considered certain.

(a) For abbreviations and acronyms, see Appendix D.

- 1958** Stannard proposes that lung be regarded as a moderately radiosensitive organ.
- 1961** "Governors' Conference" recommendations cause shutdown of some mines.
Sputum cytology program begins.
Many company representatives express disbelief in causation of health problems.
- 1960s** Animal research at Pacific Northwest Laboratory emphasizes role of other agents along with radon and daughters, e.g. uranium ore dust, cigarette smoke, diesel exhaust.
Lung neoplasms definitely seen in dogs.
Modeling lung dose becomes a full-time occupation in some quarters.
Many new instruments devised.
- 1964** Rapid increase in number of lung cancer cases in the mines reported.
Lung cancer incidence in miners six times that of nonminers.
Definitive reviews of epidemiology begin.
- 1965** Radon in natural waters from various parts of the world range from 225,000 pCi/l to barely measurable (Hursh, Rochester)
- 1966** Realization that uranium mill tailings had been used as fill dirt for dwelling foundations, in roads, etc., in Grand Junction and Durango, Colorado. PHS surveys thousands of homes, assisted by AEC. Later a similar situation was found around the phosphate mines in Florida.
- 1967** Congressional Hearings under Joint Committee on Atomic Energy.
Federal Radiation Council presents reports and recommendations—tentatively 1 WL (12 WLM per year).
- 1969** More Congressional hearings.
Czech epidemiologic study reported.
Evans "Engineers Guide" to behavior of radon daughters published.
- 1970** Bair's review of dilemmas of animal work with radon (Gatlinburg Symposium in 1969).
- 1970-1971** Interagency Uranium Mining Group report.
Secretary of Labor Wirtz decrees exposure level in mines will be 0.3 WL (4 WLM per year).
Sudden reversal from skepticism and inadequate support to a veritable bandwagon to protect the miners' health.
- 1970s** Animal research at CEA, Razès (Limoges) France. Lung tumors found in rats.
- 1972** Surgeon General issues guidelines for remedial action in areas of mill tailings use (0.05 WL for action, 0.01 to 0.05 WL advisory).
- 1973** More interest developing in doses to populations living near hot springs.
- 1976** Czech epidemiologic study reported.

- 1977-1981** Risk estimates attached to radon exposures (UNSCEAR, BEIR III, Evans et al.).
- Reviews of epidemiology of several groups of miners in the United States, Canada, and Europe.
- 1982** Chromosome aberration frequency reported for inhabitants and workers at Badgastein (Pohl-Rüling). Health-spa population declared "promising" for epidemiologic study (Wrenn).
- 1983 et seq.** Great increase in concern over population exposures to radon and daughters indoors. A major current enterprise.
- 1984** Two NCRP reports published on radon in the environment and a general review of radon. Suggestion of 2 WLM made for triggering structural alterations or cleanup of dwellings.

Chapter 3

Radon and Radon Decay Products: The Saga of the Uranium Miners

Overview

The uranium miner saga predates all of the other areas of investigation considered in this book, even that of radium. However, understanding of the causal relationships was very slow to come. Only in the post-World-War-II decades has it been possible by a mixture of laboratory research and epidemiologic studies to establish cause and effect on a firm basis and establish some rough quantitative relationships. It is a field full of dilemmas and frustrations, some of which still persist. This chapter, like the one on radium, cannot begin with or just before the Manhattan Engineer District (MED) operations. In fact, radon problems were almost totally ignored by the MED. We must go back to Europe in the Middle Ages to develop a connected story.

The chapter reviews the highlights of the miners' history in Schneeberg and Joachimsthal, the gradual development of ideas on causation, the work of Lorenz and colleagues in World War II, and then in some detail the very active period in the United States from about 1950 on involving both laboratory research and field studies. Because of the strong political overtones of the problem, the chapter digresses briefly into some of the reasons such a serious problem was allowed to develop despite previous knowledge. The parallel work with other miner populations and work abroad is reviewed briefly in order to provide a wide picture.

Because of the analogy to the iatrogenic radium cases examined in chapter 1, the chapter reviews also the story of the therapeutic spas, therapeutic mines, and other therapeutic uses of radon in both Europe and America, albeit briefly.

The recent keen interest in exposures of populations to radon and daughters, indoors and out, is taken up for completeness.

American work and U.S. government support were quite significant in the post-World-War-II era. However, the field has not been an American monopoly compared to some of the areas that arose *de novo* during the MED days and which are reviewed in other chapters.

I. Introduction

This chapter brings us into a facet of the toxicology of radioactive materials that is ancient compared to the time standards of most of the subjects in this book, complex and frustrating even to this day, yet of undeniable practical importance. The majority of the human lung cancers recorded as caused by occupational exposure to ionizing radiation have arisen in miners working where uranium was present as the primary or a significant mineral, or where the decay products of uranium and radium were carried into the working environment by water seepage or slow diffusion through porous rock. This is true even when uranium was not the mineral being sought, as was true for several hundred years.^(a)

Even the best uranium ores are far too low in content to pose any toxic hazards from their uranium content per se; nor is the external radiation dose significant ordinarily. It is the decay products of uranium that are the culprits. A glance at the uranium and radium decay series in figure 3.1 and in table 4.3 (chapter 4) should suffice for orientation. Natural uranium has a very long half-life. The first decay product of possible pertinence to the uranium miner is ^{226}Ra . But this has a half-life of 1,602 years and, as the classic story of the Curies testifies, is not easily separated from its ores. However, the next decay product, ^{222}Ra , not only has a short half-life but is a noble gas of very low chemical reactivity. It can leave the ore body or the already mined ore and enter the surroundings. This may occur either directly into the air or by release from solution if it was formed in contact with water and later exposed to air. Furthermore, the next several decay products have from short to very short half-lives. Hence, a rather considerable amount of energy can be released in relatively short times through this process.

A truncated picture of the series showing the elements of principal significance to uranium mining and related activities is given in figure 3.1.

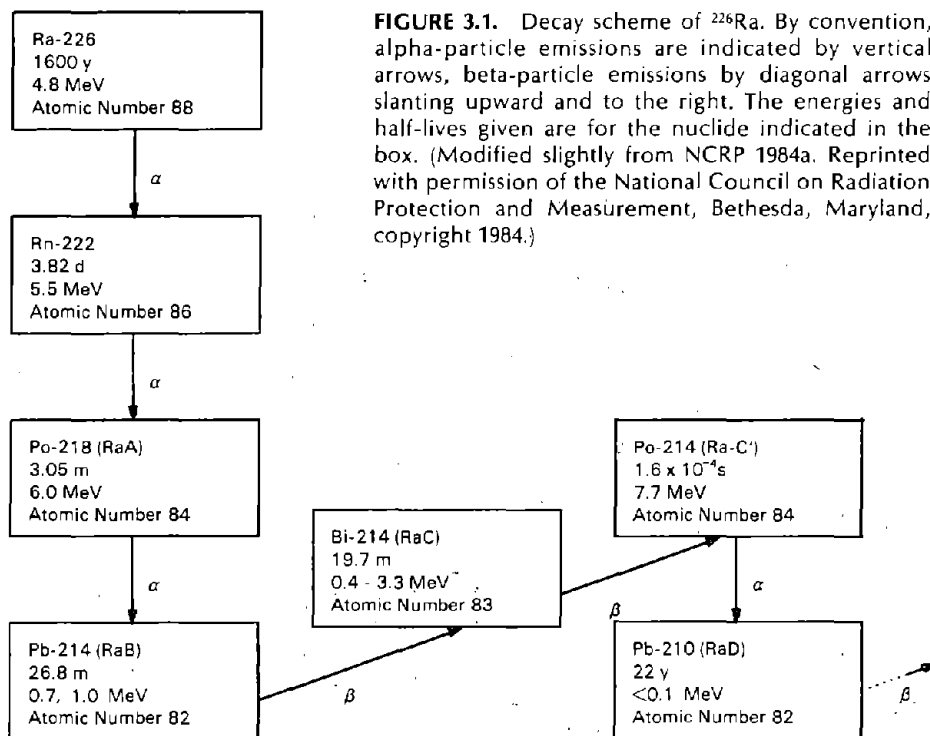

In traveling from ^{222}Rn to ^{210}Pb , over 23 MeV of potential energy are released. It is not all equally effective, as we shall see presently, but it is large nevertheless.

We reiterate. The problem of the uranium miners is not uranium at all. It is radon and its decay products (frequently called "daughter products" in analogy to the time-honored relationship of anything thought of as like a daughter in relation to its source or origin and in the same vein as "daughter cells" in biology).^(b)

Even though the decay products of radon are normally solids at ordinary temperatures, they are produced from radon one by one as single atoms. They will either attach by adsorption or electrostatic forces to ambient dust particles or, if the air is quite clean, exist transiently as free ions. Frequently there are some of both present. Thus, they may remain airborne for appreciable periods.

(a) In terms of sheer antiquity of the exposures, this chapter might be expected to carry the title "First It Was Radon" rather than putting radium first as we did in chapter 1. The reasons we do not put radon in this position are perhaps somewhat arbitrary: (1) the identification and proof of the causative agent was later than in the case of radium, and (2) radon has not occupied the bench-mark position that radium does in our thinking and research because of the many complexities of exposure, dosimetry, and effects, which we shall be examining in this chapter.

(b) Why not sons? Perhaps because the concern is with where these progeny go, and traditionally we worry more about wandering daughters than their brothers.

Radon itself is not very soluble except in fatty tissues. If breathed in, most of it is cleared back out of the blood in only a few minutes. By contrast, the decay products, if inhaled, tend to adhere to lung surfaces, remain there, or be partially absorbed and distributed to other tissues. Thus, radon itself is biologically less important than its decay products.

It is easy to see how, with such short-lived materials, conditions of exposure such as dustiness of the atmosphere, length of residence of the radon and progeny in the mine air, and the physiology of the host, among other things, make for great complexity in determining the true exposures and predicting biological effects. In sharp contrast to the solid progression from cause to effect seen with radium and with many other of the naturally occurring radioactive elements after separation from their ores, the story with radon is fraught with dilemmas and complexities.^(a)

Some of the points that seem obvious now took years to be appreciated and many more years to become established. Furthermore, in comparison with many of the other elements and situations we have been and will be examining

(a) The only one which is worse is thoron and the counterpart problems with the members of the thorium series.

in this book, radon research historically has not been intensive or on a “crash” basis. Excellent people have contributed, some have forged distinguished careers around radon problems. Nevertheless, there has never been a concentrated research effort comparable to that afforded uranium, plutonium, the fission products, fallout, etc., in the efforts of the MED or successor organizations. The ratio of the relatively rapid animal research work to the slow retrospective and prospective epidemiologic studies of human populations is probably the lowest we will encounter. Only in the last three decades toward the end of its long history is the problem receiving really adequate and concentrated attention.

Nevertheless, the amount of literature on radon problems is enormous. As the need for uranium escalated in the late 1940s and thereafter, and the number of mines and miners followed suit, we suddenly realized we faced a first-order occupational hazard with numbers of exposed individuals equal to or greater than any other population exposed occupationally to radioisotopes. There ensued some serious experimental research along with doubled and redoubled attempts to follow the exposed populations. Along with this crescendo of interest came a crescendo of meetings. There were meetings of state officials with the active scientists, ditto with federal officials, with management, state with federal, and some international gatherings. These were important and useful meetings. However, as the pressures for understanding and control mounted, so did the number of meetings until there seemed to be a radon meeting going on somewhere at almost any time. The same data were analyzed and reanalyzed, with frequently only small increments of new information. Thus, the literature grew rapidly. Some of it is in refereed scientific journals; almost all of the early literature is. All of the German and most of the Czechoslovakian literature is in refereed journals and is both good and moderately voluminous. But much of the more recent literature is to be found in enormous tomes, which are unlikely to be shelved in any but the largest university or governmental libraries. So much material had accumulated over such a short period at one point in the post-World-War-II era that one skilled and conscientious reviewer, looking at one aspect only, was driven to declare, “more has been written on this subject than is known about it!”

Now another reviewer is about to add yet another document! He will try to keep it as concise as possible by referencing the easily available literature. He is convinced that even though the field was not of great concern to the MED nor to the Atomic Energy Commission (AEC) in its early years, it is essential that it be reviewed in any book purporting to place the problems of radioactivity and health in historical perspective. Besides, we have learned some things we would have been unlikely to know if it had not been for the problems of radon and radon decay products. Also, it has been realized very recently that environmental, particularly indoor, exposures to radon and progeny may constitute the largest single source of radiation from radionuclides occurring naturally.

II. The Earlier Years in the Mines

A. Mysterious Mountains

Certain mines in Central Europe have been worked for a variety of minerals since about the year 1400. Especially noteworthy are two locations in the Erz Mountains, one in the Schneeberg district of Saxony, Germany, the other in Joachimsthal (in German, Jáchymov in the local language) in the Sudetenland.

This is now part of Czechoslovakia and is on the southern slope of the mountain range some 30 km from Schneeberg.

Miners in both areas lived a markedly shortened life. It was not uncommon for women to have three or more husbands, each of whom succumbed in the prime of life to a disease labeled *Bergkrankheit* (mountain sickness). The symptoms were varied, but usually involved the respiratory tract; then were bathed in superstition. However, some of the very earliest physicians, e.g., Paracelsus (1493–1541) and Agricola (1494–1555) linked the malady to the ores mined and discounted the role of “evil spirits.” Paracelsus labeled the disease at Schneeberg, *mala metallorum*.^(a) In retrospect, we can see that the disease presented was frequently a mixture of silicosis, tuberculosis (which was common), and lung cancer.

There are many interesting and detailed reviews of the Erzgebirge phenomena including biomedical ideas and findings, particularly in the German literature. Probably the most detailed presentation in English appears as part of the chapter on “Cancers of the Respiratory System” in the 1942 edition of William C. Hueper’s monumental volume, *Occupational Tumors and Allied Diseases* (Hueper 1942). The interested reader will find this review of both historical and technological aspects most rewarding.

We will return to these populations in subsequent sections.

B. Identification of Lung Cancer

In 1879, two German investigators, Härtung and Hesse, showed that a majority of the Schneeberg deaths were due to malignant tumors of the lung.^(b)

As recounted in many places (Hueper 1942; Stewart and Simpson 1964; and others), the work of Härtung and Hesse was followed by ample confirming evidence.

Nevertheless, identification and acceptance of the role of lung cancer hardly represented an avalanche. For example, at Joachimsthal (Jachymov) 30 km away, it was *forty-seven years* before evidence of lung cancer in those miners was published. It seems most unlikely that this was due to inattention.^(c) Härtung and Hesse made inquiry in 1879 to officials of the Joachimsthal mines as to whether or not any of the miners there had lung tumors similar to those they were seeing in Schneeberg. After all, the death rate was similarly high, and the disease descriptions seemed much alike. The answer, however, was negative. The Czech authorities stated that not only was there not any *similar* cancer, there was “no cancer of the lung at all at Joachimsthal.” Another inquiry

(a) The Renaissance physicians were quite adept at linking occupational diseases to substances and activities in the workplace. They were, of course, not as adept at mechanisms or true causation. For one recent and moderately short summary with references see Stannard (1980).

(b) Hueper (1942) points out that the correct histological identification of the tumor had to wait until 1926. Since silicosis coexisted with cancer, it seems likely that more than one cell type existed in tumors from these mixed exposures. Hence, lack of accurate identification of the histological type is not surprising. The fact that it was lung cancer was not disputed seriously.

(c) It is true that in these years the enormous health problems of the day were the infectious diseases. Health authorities might be forgiven some lack of full-time devotion to a few miners in a small mountain village, but not the events that we will see transpired later.

decades later, in 1920, still brought an official denial that any instances of pulmonary malignancy had appeared in the Joachimsthal miners. It was not until 1926^(a) that Löwy, a well-known and respected figure in Prague, reported the first two cases of lung cancer from Joachimsthal. (As we will see in section III, this was nailed down by a series of later reports, which continued until 1938.)

We can be sure that the international boundary along the Erzgebirge did not prevent the occurrence of lung cancer on the south side of the mountains for forty-seven years! The conditions, even the levels of exposure were far too similar. The real difference must lie primarily in the reporting.^(b) We can only speculate on the real reasons. The records cannot show what was *not* written down. It is hard to avoid the conclusion that either someone or some organization of the day was not willing to let lung cancer be put down as the cause of death for an unknown but significant number of Joachimsthal miners, or there was not much attention directed to the problem. Hereby we encounter one of the many obstacles that bedevil retrospective epidemiologic research: the reliability of the official record. We will meet this and related problems as we progress through this saga. Much effort was expended in later years to piece together the fragmentary records of the earlier cases.

C. Forays at Causation

The earliest ideas on causation of the *Bergkrankheit* included the metals: bismuth, nickel, and arsenic and the components of cobalt blue pigments. Each of these was called into question only to be eliminated because other mines and factories having these did not have the same health problems. For a while, as genetics began to be understood, a constitutional genetic defect in the populations was suggested. This was eliminated because the problem was limited to miners and laboratory workers exposed to the uranium ores. It did not even extend to miners in populations of other districts: similar genetically (i.e., by virtue of pedigree) but in mines with different ores. The fungi and other flora that grew plentifully in the wet mines were imputed but were eliminated by both experimental work with animals and clinical evidence.^(c) They tried everything, even feeding mud from the mines to animals along with the fungi.

Arsenic was harder to eliminate since it was a proven carcinogen. Also, the Schneeberg miners frequently showed a dermatosis of the hands similar to that seen with exposure to arsenicals. However, other miners (e.g., in France) working with high concentrations of arsenic did not yield the same symptom complex as the Erzgebirge miners. Hence, arsenic was eliminated as a *prime* cause. It still is not certain that it was or was not a cofactor. The same story holds for silica and the role of pneumoconiosis.

In 1921, Uhlig, a medical degree candidate working in the office at Schneeberg, suggested that radium and radium emanation might underlie the

(a) This is the date given by Hueper (1942, 1955) for the Löwy announcement. Others, e.g., Pirchan and Šíkl (1932), cite the Löwy paper as 1929 and indicate that one case was a factory worker observed by Dr. Pirchan, the other a miner. The published paper is dated 1929 (Löwy 1929).

(b) There were some differences in technique, e.g., fluoroscopy versus roentgenograms, but not sufficient to account for 0% versus 50% incidence.

(c) This may not be all wrong, as we will see in a later section.

difference between the Erzgebirge and other areas (Uhlig 1921). (An earlier suggestion along the same lines made in 1913 was not taken seriously.) However, it is a long road from suggestion to proof. An early response was to turn to actual measurements of the radon content of the mine air (e.g., Ludewig and Lorenser 1924). It was definitely elevated in both Joachimsthal and Schneeberg. Furthermore, certain areas that had become known as "death shafts" because of the unusually high occurrence of lung cancer in men who worked in them were found to have especially high concentrations of radioactivity. Furthermore, there were the facts that epidemics of the disease seemed to follow the trails of workers present when a new especially rich ore vein was opened, and drillers and hewers were the most frequently affected class of workers at Schneeberg. These men are the first to come in contact with newly fallen ore and newly opened stopes. Finally, mines in the Johann Georgenstadt district, which had characteristically low incidence of the disease, had relatively low contents of radioactivity in air and water.

Another step toward establishing causation was experimental work. Some very early Russian work (London 1904, cited by Kushneva 1962) indicated toxicity of radon to frogs and white mice. The experiments were acute, and the effects measured appeared largely in peripheral blood. (These may well be the earliest experiments with radon in animals.) Probably the first animal experiment undertaken directly in response to the high incidence of lung cancer among the European miners was that of Jansen and Schultzer (1926), cited by Morken (1955c). This was followed by many experiments from Rajewsky's Institute in Frankfurt, e.g., Read and Mottram (1939), and many others, which we will review briefly in section VIII of this chapter.

Unfortunately, most of the animal exposures were at quite high levels, and the composition of the aerosol with respect to dust, fraction of equilibrium with the daughters, etc., was not controlled because by and large these factors were not appreciated as being important. Some of the German work (Rajewsky) suggested possible increases of lung cancer in mice (but this was complicated by intercurrent illnesses in both experimental and control animals) and some thickening of the bronchial epithelium in the controls. Most of the work did not show lung or other cancers. The levels of exposure were too high and the observation periods too short.

Except for proving that radon as "radium emanation" could be highly toxic, these early experimental tests with animals did little toward confirming the causation of the lung cancers in the Erzgebirge miners. The best of the studies provided suggestive histological changes, but no more. The most convincing proof for Uhlig's guess was the correlation between cancer incidence and radioactivity measurements in the mines. Yet, the correlation was crude and left many loopholes for those with other ideas.

This is roughly how things stood after a period of about four hundred years, i.e., a good description of the disease, a few ideas on control (to be mentioned later), and a shrewd guess, but no complete proof concerning causation.

III. The Middle Years in the Mines

The "early years" discussed in section II encompassed from approximately the fifteenth century to near the end of the decade of the 1920s. It was obvious that research and clinical observations were reaching a new phase of both activity and understanding in the late 1920s. The next decade was sufficiently different

to warrant consideration as an entity even though the changes were as much attitudinal as scientific. Unfortunately, the prodromal phenomena of World War II truncated sadly some of the most active programs of the 1930s, well before the hostilities themselves began. The war halted all such work in Europe, of course.

The mine populations studied were from the same two locations, Schneeberg and Joachimsthal. Many of the miners had been pensioned off by this time, but remained by and large in their native villages. These "pensioners" contributed much of the information gained in this period. Experimental work increased considerably, and measurements and measuring devices for mine atmospheres received much more attention.

A. Accumulating Information on the Miners

The German work that followed Härtung and Hesse in 1879 continued into 1938. Because of the continued relative isolation of Joachimsthal, most of the work in the 1920s and early 1930s involved the mines at Schneeberg, with some work at other German mines known to have different properties. The basic findings remained about as in the previous period, except that more correlation between radon levels and locations of effect accumulated. Correlations with age, years of employment, and time of exposure were methodically investigated. The clinical course of the disease and its pathology were described in some depth, as nicely summarized by Hueper (1942). It became apparent that there were really at least two diseases coexisting—the silicotic process and carcinoma. These frequently interfered with each other in terms of reliable x-ray diagnosis and interpretation of symptoms. Only post-mortem examination, both gross and microscopic, could supply the clearer picture needed. On the whole, the work at Schneeberg became relatively sophisticated by the standards of the day. The fact that these cancers could have long latent periods became quite apparent.

In contrast to the relative silence from the Czechoslovakian side in the 1920s, the 1930s saw some complete and scholarly reports. The best source for our purposes is the paper by Pirchan and Šikl in the *American Journal of Cancer* (Pirchan and Šikl 1932). The work came from the State Radium Institute at Jachymov and the Czech University at Prague, but it was published in an American journal. Reading between the lines indicates that the authors had their reasons for choosing a foreign journal. There is reference therein to earlier frustrated efforts to bring the matter of lung cancer to the attention of either the mine administration of Jachymov or the national health authorities. Things seemed to change only when Dr. Pirchan became Chief Physician of the Jachymov Radium Institute.

The first work from Czechoslovakia chronicles examination of eighty-three persons and a critical study of nineteen miners who died in the period 1929 to 1930. Post-mortem examinations were made on thirteen, of which nine had lung cancer. All had severe respiratory problems in their later years. Detailed case histories are given along with gross and microscopic pathology. In general, the story resembled Schneeberg's, but the cancer, once started, seemed to progress more rapidly and be more malignant.^(a) Hueper comments on the slower progression of the Schneeberg cancers. There was more dust at Schneeberg. This

(a) For the comparison with Schneeberg, the authors used primarily work by Rostoski, Saupe, and Schmorl (1926).

has led some to postulate that the accompanying greater silicosis and greater blockage of lymphatic vessels slowed the spread of the cancer relative to the Joachimsthal cases.

The work in Czechoslovakia was continued by others during 1933 to 1934 and increased in 1934 to 1935 after the government agreed to provide an indemnity to the relatives of the deceased if an autopsy was permitted: Incidence of lung cancer in the miners was steady at about 50%. (The figure had climbed to 75% to 80% in Schneeberg by this time.)

There was in 1935 an official Czechoslovakian government report that based its conclusions on the regular medical examinations (physical, x-ray, and laryngological) of the miners. It contended that only four lung cancers had occurred over the period 1932 to 1935. They pointed to improved ventilation of the mines as responsible for the low rate, forgetting that three years is very short in relation to the known latent periods for lung cancer. Others analyzed data from the Czechoslovakian Ministry of Health from 1929 to 1938 and found the mortality from lung cancer was far higher (as much as twenty times higher) than that in corresponding populations of Prague and Vienna. Thus, we see a continued tendency on the part of the government to play down the incidence and importance of lung cancer.

In further work in the Czech mines, the influence of age, time of exposure, type of worker affected, etc., were analyzed and documented. Except for problems of science versus officialdom and the inherent difficulty of the work, the Czech studies had become very useful and promising.

By 1932, both Germany and Czechoslovakia had made lung cancer a compensable occupational disease. This helped in tracing workers who might otherwise have lost contact by adding the stipulation of mandatory periodic medical examinations.

Measurements of airborne radioactivity in the mine air and water increased greatly. These helped toward establishment of causation. The work did not make any attempt at the ultimate test, establishment of a dose-response relationship. A summary table taken from Bair (1970) shows the composite figures for cancer incidence in the European mines in the entire pre-World-War-II period, i.e., 1875 to 1939 (table 3.1).

The incidence of lung cancer is indeed startling when seen from this retrospective view.

TABLE 3.1. Lung Cancer in Schneeberg and Joachimsthal Miners

Location	Period of Study	Number of Miners	Number of Miner Deaths Studied	Number Having Lung Cancer	Percent Lung Cancer
Schneeberg	1875-1912		665*	276	41.5
	1922-1925	154	21	13	61.9
		353†		2	
	1936-1939	70	6	5	83
Joachimsthal	1928-1938		89	43	48.3

* 119 died of other lung diseases.

† Factory workers and residents of surrounding county.

B. Closing in on Radon

The work of Pirchan and Šikl (1932) already discussed and of Šikl (1930) seems to be generally considered a landmark in pointing to the radioactivity of the mine and laboratory air as a principal causative factor for the disease of the miners. This occurs despite the fact that the idea was suggested earlier for Schneeberg by Uhlig (1921) and by Ludewig and Lorensen (1924). Like all such matters, the progression from suggestion to general acceptance was slow and tortuous. Perhaps the Pirchan and Šikl work is most often cited because it is very complete and very well documented. Also, it is in English!

Attribution to the various metals, particularly cobalt and arsenic, hung on for many years but was gradually moved from primary cause to secondary cause to possible cofactor status. The coexistence of silicosis was almost always a complicating factor in the miners at Schneeberg. As detailed by Hueper, the introduction of pneumatic drilling, which increased the dustiness of the air, led to the idea that the later neoplasms resulted from *radium* attached to silica particles. It was proposed that the silica started an inflammatory process, which was "activated" to a malignancy by the radioactivity from the radium. The argument against radon was that the period between shifts in the mines (about seventeen hours) allowed for complete removal of the radon from the body. This was backed up by laboratory work which showed that all radon inhaled was removed in seven hours. Further, measurements of tissue radioactivity in autopsy material and after animal exposures showed that very small amounts of radioactivity remained, and what was present appeared to be from radium.

Even the idea for a role of radioactivity from radium was given a serious setback when the amounts of radium found were compared to what Flinn (see chapter 1) stated was a hazardous amount of radium (isotope not specified). Flinn's figure was 1.5×10^{-6} g radium equivalent, while the amounts found in the tissues from miners were 1.5×10^{-8} g radium equivalent in one estimate, 1.5×10^{-12} g in another, less than 10^{-12} in still another (Rajewsky 1939). The conclusion was that the radioactivity was too low to play an important role. Tschelnitz (e.g., 1935) was a strong advocate of the innocuousness of the radioactive component of the inhaled air (Heuper 1942).

Others did not share the negative attitude of Tschelnitz. Their views were based on the extent of the cumulative exposure to radon, that over ten years might be equivalent to 15.5 to 31 mg of radium. In addition:

1. It was shown that dust inhalation and silicosis were not a necessary condition for malignancy, at least not at Joachimsthal.
2. Blood changes seen in the miners and in experimental animals were reminiscent of radiation-induced changes in the early highest dosage groups of the radium dial painters and in animals receiving x-ray doses. The correlation was not striking, however, nor was there any quantitation.
3. Correlation of radon content of specific work areas and development of the pulmonary syndrome seemed real. This was the strongest link to the uranium ore and radioactive materials. Correlations between the opening of rich new veins and of working in certain shafts known to have richer uranium ore than others and the incidence of lung cancer were quite positive.
4. Lung carcinoma occurred in laboratory employees engaged in extraction and purification of the radioactive substances from the ores. Very little dust or silicosis was present in these cases, but the radioactivity was present.

Reasonably good, though cumbersome methods for measurement of radon in mine, laboratory, and industrial air were developed in Europe during the years under discussion. Ludewig and Lorensen are credited with the critical measurements at Schneeberg, Böhme (1936) with those at Joachimsthal.

A summary of their measurements, converted from the Mache units of the day to curies^(a) by Evans and Goodman (1940) is given in table 3.2.^(b)

Identification of the mines and shafts in table 3.2 must be left to the perusal of the original literature, except to state that the "Turkschacht," which had some of the highest readings, was among the more notorious locations for lung cancer cases. Note also the large range in the values. This does not mean sloppy technique. It reflects the sometimes large differences in radioactivity at different locations in the same mine. This is related to the degree of ventilation and location with respect to the highest grade ore.

While a direct cause-effect relationship remained somewhat tentative, more and more investigators became convinced radon and airborne radioactivity were the primary causative agents for the lung cancers. Those remaining unconvinced were influenced in part by the failure to produce the lesions in experimental animals and by the low radioactivity of the tissues of deceased miners.

TABLE 3.2. Summary of Published Data on the Radon Content of the Air in Various Mines of the Schneeberg and Jachymov Districts

Mine	No. of Samples	Radon Concentrations per Liter of Air	
		Range	Average
		10^{-11} Ci	10^{-11} Ci
<i>Schneeberg (1923)</i>			
Weisser Hirsch	9	60-320	190
Türkschacht	5	40-1800	550
Neujahrsschacht	8	120-220	160
Siebenschlehen	6	200-870	560
Beustschacht	7	70-180	110
<i>Jachymov (1924-25)</i>			
Einigkeitsschacht	6	30-180	80
Wernerschacht	6	230-880	500
Average of all individual samples	47		290*

* Because of the high values observed at a few points in the mines, the arithmetic average of all individual samples is greater than the median value, which is 180×10^{-11} curies per liter.

Source: Reset from Evans and Goodman 1940. Reprinted with permission of the American Occupational Medical Association, Arlington Heights, Illinois, copyright 1940.

(a) 1 Mache unit = 3.64×10^{-10} Ci/l = 3.64 Emans/l = 364 pCi/l.

(b) Note that these particular measurements were done in the 1920s and thus preceded some of the biomedical correlations we are reviewing here. Many more measurements were reported in the 1930s by the German investigators.

Radon measurements were, of course, being done also in the Western Hemisphere. Some were part of the study of radium patients and workers (see chapter 1). Many were accessory to the radium emanation facilities for production of radon seeds for use in radiology. Some were directed toward factory workrooms and involved thoron, as well as radium and radon (Evans and Goodman 1940). Some were done on breath samples from members of the Armed Forces working in the presence of large arrays of luminous dials painted with paint containing radium (Evans, personal communication 1981). In most cases, the samples were collected in evacuated flasks and, before World War II, sent for analysis to one of the major laboratories. In the United States, these were primarily the National Bureau of Standards (NBS) and Massachusetts Institute of Technology (MIT).

The early measuring devices were large (3-l) ionization chambers. Special precautions were needed to purify the gases used for sweeping the radon sample into the chamber, since for high sensitivity, as low backgrounds as feasible were necessary for the measurements. A description of a typical apparatus for radon, radium, and thoron is to be found in Evans (1935).

Thus, the research during the period 1929 to 1940 moved a considerable distance toward understanding what was going on. There were many who were convinced that radon was the causative agent. There were still problems, however, particularly as the field of radiation dosimetry matured. The calculated doses to whole lung seemed too small to produce the effects seen in comparison to radium doses, which were unfolding in parallel, and to external radiation doses associated with carcinogenesis. There either had to be another factor, or there was some mistake. As we will see in section IV C, the problem was that they *measured only radon and thought only radon*. In what might now be labeled male chauvinistic fashion, they did not focus on the daughters or give them their due!

C. The First Standard

Most of our discussion of exposure and intake standards for radioactive materials is being reserved for chapter 16. The development of standards for radon, and later radon plus its daughter products, is so intimately entwined with the development of ideas and progression of the research that we must make an exception and discuss standards briefly here along with the rest of the story.

In 1941, the first two authoritative standards for radioisotopes in the body were developed. The first was for ^{226}Ra , as will be detailed in chapter 16. The second was for radon. It was derived almost entirely from the work of Evans and Goodman (1940), although it was officially promulgated as a recommendation of the U.S. X-Ray and Radiation Protection Committee of which Evans was a member (NBS 1941).

An examination of data in many different situations led to the conclusion that an average radon concentration in the Schneeberg and Jachymov mines might be taken as 2.9×10^{-9} Ci/l. In round numbers, it was concluded that prolonged inhalation of an atmosphere containing radon at $\sim 10^{-9}$ Ci/l (1,000 pCi/l) could be considered associated with an increase in lung cancer in the miners. Keeping in mind differences in individual radiosensitivity and in the absence of a true dose-response relationship, a factor of one hundred was introduced for safety.

Thus, it was concluded that a safe level for the radon content of the air in plant, laboratory, or office was 10^{-11} Ci/l (in the terms we now use, this is 10 pCi/l).^(a)

While not quite as rock solid as the limiting radium body content figure proposed at the same time, it will be clear by the end of this chapter that this recommendation for radon is close to what we accept currently—except for the complications of the role of the daughter products. But there were to be many intermediate steps—some of them acrimonious hassles of as much political as scientific content.

IV. The Later Years in the Mines and Mills

The period we now enter extends from approximately 1942 to the cutoff point for this chapter—approximately 1984. We add the uranium mills since they became a factor of some significance in these years. However, we will focus still on occupational exposure and save the population and environmental counterparts for separate discussion.

A. The World-War-II Years

The years of World War II were a quiet era for radon research. In Europe no real research was reported. In the Western Hemisphere, measurements needed to be made for radon exhalation by those carrying radium body burdens (chapter 1). Further work was done on radon exhalation from armed services personnel, and, of course, the medical calibrations had to continue.

The radon measurements in the United States continued to be done largely at the NBS and at MIT. However, in perusing old files, this author ran onto a letter signed by Dr. (Maj.) H. L. Friedell (whom we met in the preface to this book) authorizing analyses of radon by the Rochester Project on samples submitted by the University of Chicago (Friedell 1944). This was preceded by a letter to J. J. Nickson in Chicago from W. F. Bale at Rochester that stated the probable error of the method and indicated that it was not sensitive enough to determine radium content of the normal human body by expired breath measurements. The letter does not state what the samples were or for what purpose (Bale 1944). They were not numerous.^(b)

The draft manuscript copy of the book prepared by Dr. Friedell (1981) and very kindly provided to this author by him makes no mention of radon work anywhere in the Manhattan District Laboratories. Obviously it was a low-key subject.

There was one exception, however—a major one. Dr. Egon Lorenz at the National Cancer Institute (NCI) in Bethesda, Maryland, was asked by the Met Lab to carry out a large and relatively long-term experiment on the carcinogenesis in mice of a graded series of relatively low levels of x-irradiation.

(a) This standard was not intended to be applied to the mines. The Europeans were totally involved with the war. In the Western Hemisphere, there were not yet enough uranium mines *per se* to worry about exposure standards. Uranium mining in the United States had hardly begun. The standard was intended for laboratories, factory work rooms, or offices in installations handling radium, producing radon seeds, and the like.

(b) It is the author's conclusion that the samples involved workers at the Eldorado Radium refinery across Lake Ontario from Rochester at Port Hope, Ontario (Hurst 1978).

Perhaps because of his past interests in radioisotopes, including a review of the Schneeberg and Joachimsthal cases (Lorenz 1944), Dr. Lorenz also studied short- and long-term effects of radon. His primary focus was a comparison of the effectiveness of alpha particles (high-linear-energy-transfer [LET] radiation), with photon radiation such as x rays (low LET) in a higher vertebrate.

The radon was given by intravenous injection (not by *inhalation*) of a solution of radon in *equilibrium with its decay products*. Doses were high (0.013 to 0.017 mCi/g). Acute toxicity was compared with x-irradiation doses of 480 to 645 roentgens. (When converted to energy absorption, the RaC' alpha particles, considered the primary source, contributed from 33,800 to 44,200 erg/g, while the calculated x-ray doses gave 44,600 to 60,000 erg/g.) The LD₅₀ for thirty days in the animals receiving the radon solution was about 1.42 times lower than that for the x rays (Hollcroft and Lorenz 1951). This was in the right direction in view of the relative biological effectiveness factors for alpha particles, which were emerging from Met Lab work with isolated cells and organisms. However, it was in no way comparable to the large difference in effectiveness seen in single-celled systems.

This discrepancy led the Lorenz group into a careful study of how the decay products of radon were distributed in the animal by performance of a fairly extensive tissue distribution experiment involving about three hundred mice. The short-lived decay products were found to be distributed very unevenly among organs (they measured twelve entities) and so were the calculated doses. Kidney, intestine, and blood were far ahead in contribution of ergs per total tissue in a 25-g mouse. The total dose calculated from all of these separate analyses was only 3% below the expected dose—a good testimony to the technique.

When tissue weights were taken into account, most tissues got about the average radiation dose, except for kidney, which was about fourteen times higher than the average.

Lorenz had to admit that the outcome of the LD₅₀ comparison was difficult to understand but did not remark upon the possible role of the effects of daughter products. Nevertheless, this was beautiful pioneering work, and the first careful study this author knows of where the behavior of each decay product and the sum of RaC and C' was measured and its contribution to tissue dose spelled out. Thus it is a landmark. It introduced the whole new era of considering the contributions of the decay products formed in the body after radon inhalation.^(a) It correctly showed that radon itself contributes only about 2% of the total dose from an equilibrium mixture and that the RaC + C' contribution predominates.

A second report from the Lorenz group (Hollcroft et al. 1955) followed up on the high dose to kidney noted earlier. A unique alteration of the kidney cortex occurred. It was somewhat similar to that being noted at about the same time by Casarett (1952),^(b) from the passage of ²¹⁰Po through rat kidney. It differed from the nephrosclerosis seen after x rays. This work went to over two hundred days and gave an opportunity for more long-term effects to show. But a small serial sacrifice experiment failed to demonstrate any preneoplastic or neoplastic changes.

(a) Others had indicated awareness of the problem, but this was the first quantitative evaluation so far as this author knows.

(b) This radon work was actually done slightly postwar, but it follows the Met Lab work so logically that we discuss it here. The Casarett work was done during the war, but reported early postwar (see chapter 4).

The work on radon from Lorenz's laboratory is obviously a milestone by focusing on the dosimetry and daughters. While it had only indirect bearing on the uranium miner saga since the route of entry was intravenous, it represents much tedious measurement and some original thinking. As the primary contribution to radon research from the MED days, we can be happy it is of such high quality.^(a) Lorenz calculated radiation doses to lung and concluded that they were insufficient to account for lung cancers in either animals or man.

About the only other event in the radon field during World War II worth mentioning, in addition to the necessary routine measurements, was tinkering with the maximum allowable concentrations by factors of five to ten. These occurred in Canada and the United Kingdom as described by Stewart and Simpson (1964).

B. New Populations to Study

1. Miners

Uranium ore was mined from the late nineteenth century on in the western United States for the extraction of radium,^(b) for use of the uranium as a coloring agent in bottles and ceramics, and during the 1920s and 1930s, for preparation of vanadium. This continued into the 1940s.^(c) During World War II, there was a gradual shift toward use of the ore for nuclear energy. Mines that had been worked primarily for vanadium ore by the U.S. Vanadium Corporation and the Vanadium Corporation of America were found to contain promising, though not exceptionally rich, uranium ores. (Many of the best veins had already been depleted for the production of radium.)^(d) Contracts were let in 1942 between the MED and these and other corporations for production of uranium ore and compounds from both the reopened mines and the tailings and sludges from the vanadium process, which contained uranium and radium in various amounts.

It seemed unlikely, however, to the planners in Washington that these sources could supply sufficient uranium for even the first phase of either the electromagnetic or the gaseous diffusion processes. The OSRD^(e) turned to collaboration with Canada for opening up deposits at Big Bear Lake in northern Ontario through the Eldorado Gold Mines, Ltd. They had supplied uranium ore

(a) Undoubtedly, other good work was done during the war years, both in the United States and abroad. However, we must hew closely to our charter for this book.

(b) There was a radium extraction plant (Radium Company of Colorado) in Denver from the turn of the century until 1924, for example.

(c) An interesting account of all of these operations can be read in the book by Kathleen Bruyn, *Uranium Country* (1955).

(d) It is often stated that Madame Curie used carnotite ore from the United States in her radium work before the far richer ores from the Belgian Congo took over. Evidently, Schneeberg and Joachimsthal were supplying rather low-grade ore. A booklet issued by the Union Carbide Corporation (1952 et seq.) is quite positive on the role of U.S. ores in Curie's work. Others are not so certain. The Colorado ore also got to the Standard Chemical Company processing plant in Canonsburg, Pennsylvania, and it is reputed that they made a gift of radium to Madame Curie for use as a standard in her later work. In any event, uranium mining in the Colorado Plateau was not a completely new phenomenon at the time we are now considering.

(e) Office of Scientific Research and Development, the original organization for World War II Scientific Planning and contractual support.

for some years for preparation of radium at a plant at Port Hope on the shores of Lake Ontario. Arranging to get ore from Canada, without breaches of security, took a bit of doing, but it came about.

Meanwhile, a source of overwhelmingly superior uranium ore from the Belgian Congo was somehow overlooked, albeit temporarily.^(a) The Belgian combine "Union Minière du Haut Katanga," which controlled the African Metals Corporation, had, through the foresight of Edward Sengier, its ranking officer, brought twelve hundred tons of high-grade uranium ore to the United States in 1942, "to keep it out of enemy hands." (How did he know the Americans would need it?) It was stored on Staten Island in New York Harbor. There were, in addition, about three thousand tons of equally high-grade ore already above ground in the Belgian Congo, and arrangements were made to buy it. Most of the shipments of this ore, which could masquerade as ballast for westward-traveling freighters, reached North America despite the hazards of the German U-boat campaign.

By the end of 1944, the U.S. Army had about six thousand tons of uranium oxide; two-thirds of it from the Congo ore, one-sixth from Canadian pitchblende, one-seventh from the Colorado Plateau, and the balance from miscellaneous sources such as tailings.^(b,c)

The activity just described was the beginning of burgeoning uranium mining activities in the Colorado Plateau area of the United States and in northern Canada. As domestic demand for uranium grew, the number of mines grew to over twenty-five hundred in the Colorado Plateau alone by the mid-1950s. Some were large operations, such as the former vanadium mines. Some were one- or two-man operations.

As a result, there were new and retreaded populations to study. Indeed, the total is now seven. Besides the U.S. and Canadian uranium miners, the active population of Czechoslovakian uranium miners was studied intensively. They did their mining in the period 1948 through 1957.

Quite obviously, with so much attention being given to radon, many measurements of radon activity were made in a variety of mines not being worked for uranium. Many other hard-rock mines were found to have from significant to quite high concentrations of radon and radon daughters. This led to a study of quite disparate groups in many countries.^(d) These include:

1. lead and zinc miners in Zinkgruven, Sweden
2. iron miners in Kiruna and Malmberget, Sweden

(a) This was the ore that had preempted those of the Colorado Plateau and even those of Schneeberg and Jáchymov and had caused the former to shift to vanadium extraction.

(b) A more complete history of these phases of the OSRD, MED, and other efforts can be found in the first volume of the official history of the U.S. Atomic Energy Commission (Hewlett and Anderson 1962).

(c) It is hard to resist the view that the foresight of Edgar Sengier and his business acumen (he did plan to sell the ore) aided the MED effort very significantly. We were short of miners, many of the mines were filled with water and took months to get back into operation, and it was in toto a slow process. Sengier deserves more than perfunctory recognition. For further comments on Sir Edward's contributions, see the chapter, "A Thousand Years of Regrets," in Lewis Strauss's book cited in Appendix B.

(d) The groups making epidemiologic units are U.S., Canadian, and Czechoslovakian uranium miners; Swedish and British iron miners; Swedish lead and zinc miners; and Newfoundland fluorspar miners (section VI).

3. fluorspar miners in Newfoundland
4. underground iron miners in Britain and France
5. base metal and hard-rock miners in the United States
6. gold miners in South Africa
7. manganese miners in the USSR.

In all but the last two cases, excess incidence of lung cancer has been reported, but definite linkage to radon exposure was quite uncertain in some of the populations. However, the epidemiologic evidence became strong in the U.S. and Czechoslovakian studies, very suggestive but subject to more uncertainties in the Swedish miners, Canadian uranium miners, and Newfoundland fluorspar miners.

The details of these studies are part of a vigorous scientific polemic at present because of the complexities of cigarette smoking and other potential cofactors. We will enter this arena and take up the results of these epidemiologic studies in section VI.

2. Millers and Others

There were many large dumps left over from the prewar radium mining operations. These were reworked for uranium. Also, during the MED days, the uranium ore went for processing to many of the facilities that had been concerned with handling the ore for other purposes, e.g., for extraction of vanadium, radium, etc. Thus, some of the Canadian and high-grade Congo ore went to the Port Hope radium refinery, but not for extraction of radium. The Mallinckrodt Chemical Company plant in St. Louis had the pleasure of trying the tricky ether extraction on an industrial scale. Many American ores went to plants already under government operation for vanadium processing, e.g., Durango and Grand Junction, Colorado; while later high-grade Congo ores went to the Vanadium Corporation of America plant at Canonsburg, Pennsylvania. The Linde company worked on sludges from the U.S. Vanadium Corporation and later low-grade African ores at its plant in Tonawanda, New York, along the Niagara frontier.

Each of these had somewhat different processes to carry out. (Remember the MED was running on several parallel tracks.)^(a) Personnel exposures to radon and its daughters ranged from negligible to significant. Exposure to radium and uranium *per se* as well as radon and its daughters was fairly common.

Many of the buildings used for these operations are now both obsolete and contaminated. Some have been demolished, leaving a contaminated site. Consideration of these has required a significant effort in environmental and laboratory research (chapter 11).

V. Dosimetric Problems

Before we can profitably review, even briefly, the epidemiologic significance of the several populations described above, we must enter upon the problems of dosimetry. These always have been and still are one of the most difficult aspects of the radon saga.

(a) Hewlett and Anderson (1962) review details of locations and processes, and an overview of the several "tracks" can be found in Smyth (1948).

Necessary allusions have been made already to early considerations of lung dose. Obviously, calculations made before the establishment of radiation dose and exposure units (i.e., in 1927) are difficult to interpret in terms of rad or rem (or grays or sieverts), even though some have been translated to modern concentration units (e.g., curies per liter, see table 3.2).

There are three basic problems in the dosimetry of radon and daughters that have occupied researchers and operators alike. These are, simply stated:

1. What role do the daughter products of radon play? How can their contribution to dose be ascertained?
2. What is the "target" tissue—whole lung or some portion thereof?
3. How can one measure a mine atmosphere in terms that bear a quantitative relation to potential radiation dose and thus biological effects?

Detailed analysis of the research and arguments surrounding each of these questions would carry us far beyond the bounds of available space. Let us, however, consider each briefly with emphasis on historical origins of the ideas.

A. The Role of the Daughters

We have already remarked on the stubborn tendency of the early investigators to neglect the daughters. Even after measurement techniques became reliable and relatively simple, it was usually ^{222}Rn that was measured. The decay scheme had been worked out in the early years after the separation of radium. People knew there were daughters, but only the most careful workers went to any real pains to characterize their atmospheres in terms of "free of daughters," "in equilibrium with daughters," etc. As we have already seen, Lorenz's work toward the end of World War II put the finger firmly on the fact that radon itself contributed only a few percent of the dose from an equilibrium mixture.^(a) Yet, investigators were still thinking of daughters formed *in vivo* after inhalation or other mode of entrance. The radon standard of 1941 (see section III C) was in terms of curies of radon gas per liter, and routine measurements hewed closely to that concept.

Then came one of those "quantum jumps" in thinking that we tend to associate more with the physical than with the biological sciences. In the early 1950s, William F. Bale, Professor of Radiation Biology and Biophysics at the University of Rochester, accepted a temporary assignment in Washington with the Division of Biology and Medicine of the AEC. This was in the years when AEC was first beginning to realize it might have some responsibilities for uranium miners.

Evidently Bale was either set to work on the radon problem or set himself to work on it. The result was a document labeled simply "Memorandum to the Files, March 14, 1951: Hazards associated with radon and thoron" (Bale 1951). This completely revolutionized the dosimetry of radon and thoron! It was never published until the twenty-fifth-anniversary volume of *Health Physics* (Bale 1980). Like all such advances, the idea seems so simple we wonder how it could have been missed for so long, but it was. The point can be made best by quoting the author:

In these and other past evaluations of the hazard associated with radon the vital fact seems to have been almost or entirely neglected that the radiation dosage due

(a) There were others, but their fingers were not as firm.

to the disintegration products of radon present in the air under most conditions where radon itself is present conceivably and likely will far exceed the radiation dosage due to radon itself and to disintegration products formed while the radon is in the bronchi. (From Part II of Bale 1951)

The key is the phrase "*present in the air.*" All but the most artificially cleaned air will have dust particles upon which the decay products produced *outside of the body before inhalation* can adhere. If the air is quite clean, the decay products can exist transiently as free ions. Both of these will be inhaled along with the radon and can contribute greatly to the dose to lung. Bale calculated, for example, that the total RaC' energy delivered to the lungs from an inhaled mixture of radon along with 50% of its equilibrium level of daughters would deliver a radiation dose about seventy-six times greater in terms of total alpha-ray energy liberated in the lungs than would be calculated on the basis of simple equilibrium of radon with its daughter products *produced in the lung*.

Major steps in science seldom occur in complete isolation. This was no exception. John Harley, who had been working for some years at the Health and Safety Laboratory of AEC in New York, decided to complete his Ph.D. work and incorporated almost identical ideas to those enunciated by Bale in his memo to the files. They were in his thesis at Rensselaer Polytechnic Institute in Troy, New York. The work was condensed in a paper in *Nucleonics* (Harley 1953) with emphasis on sampling. The abstract reads as follows:

Abstract—Inhalation of radon daughter products can be more hazardous than inhalation of radon itself. A method is described for simple, rapid determination of radon and its daughters for concentrations as low as 5×10^{-15} Ci/l.
(From Harley 1953, 1980)

Since Harley was a frequent visitor as a consultant to the AEC Headquarters, it is presumed that he and Bale discussed their mutual ideas well before Harley completed his thesis. Bale is usually given credit for the idea because his written version was in 1951, while the Harley thesis and publication were later. It is quite likely that this important step forward was indeed a joint one. Since neither man has made any point of establishing priority, we will not attempt to go further into who was primarily responsible. Probably the idea "just grew" in both minds.

When Dr. Bale returned to Rochester from his Washington assignment, he and Jacob Shapiro, his graduate student and later colleague, set about evaluating experimentally the ideas generated in the memorandum to the files. He and Shapiro exposed animals and humans to radon at various fractions of equilibrium with preformed daughters, in quite clean, normal, and very dusty atmospheres. (The dirtiest carrier atmosphere was supplied by a sparking electric motor.) These experiments supported completely the importance of inhalation and retention of preformed daughters (see Bale and Shapiro 1956; Shapiro 1956; and for more detail, Rochester Project Reports by Shapiro and Bale 1953; and by Shapiro 1954).

Two tables, taken from Bale and Shapiro (1956), illustrate the experimental results. Table 3.3 shows average doses from alpha radiation to lungs and tracheae of rats from radon and daughters in different laboratory-created environments.

It is interesting to note that the experiment shows little difference in average dose to lung between normal outdoor air and the "dirtier" air with electric

TABLE 3.3. Average Radiation Doses from Alpha Radiation to Lungs and Tracheae of Rats Breathing Radon Plus Radon Degradation Products at Radon Concentration of 1×10^{-11} Curies/cm³

spark nuclei. There were evidently already enough dust particles present to act as carriers. Also, in the rat, the average dose to lung was much lower in cleaned air, but the dose to tracheal epithelium was almost the same in stagnant cleaned air as in normal outdoor air. By contrast, stirred clean air produced a dramatic lowering of both average dose to lung and average dose to trachea.

Table 3.4 shows some of the information from the dog. Here the average dose to lung was lower, but that to trachea was about the same as in the rat in normal outdoor air, considerably *higher* with electric spark nuclei, in contrast to the findings in the rat.

Bale and Shapiro checked out two human subjects by measuring retention of inhaled radon-daughter products in a chamber. Normal air was compared to artificially cleaned air.

These experiments and others in the quoted references were enough to convince all concerned of the importance of the daughters and also of the importance of the anatomical dimensions of the airways. Thus, the dog trachea was a better surrogate for man than the structures in the rat.

These ideas and their confirmation had their impact on the regulators and others concerned with radiation protection standards. As recounted by Stewart and Simpson, the calculated dose from the same measured pure *radon concentration* when inhaled decay products were added was about two thousand times higher than predicted by Evans and Goodman in 1940; three hundred times that

predicted by Mitchell's calculations in 1945, which involved equilibrium with the daughters found in vivo; and about ten times the values predicted by Evans in 1950.

Morgan was among the first to suggest altering the allowable exposure level to radon (Morgan 1951; 1954). In the second memo, he utilized the implications of the Bale-Harley bombshell. Naturally, some of the accepted levels that were thought to have comfortable factors of safety now came uncomfortably close to the maximum permissible dose rate. We will have to leave details to those who are now summarizing the history of radiation protection.

B. The Dose to Lung

Even before the change in viewpoint on the role of the daughters, the assessment of radiation dose to the lung had created problems. We have already seen that early calculations of dose using radon alone, even radon plus some of the daughters produced in vivo and "plated out" on the walls of the respiratory tract, were considered too low to account for the effects seen. This is well-summarized in the excellent paper by Stewart and Simpson. The Bale-Shapiro work plus animal studies at the Naval Radiological Defense Laboratory by Cohn, Skow, and Gong (1953) clearly raised the dose, even the average dose to the lung, to levels consistent with the damage seen. In addition, their work showed that the ratio of dose rates averaged over the whole lung to those to the bronchial epithelium could range from about unity when radon and daughters were inhaled in ordinary outdoor air in the rat to about 1:8 in the dog. They chose for man a ratio of bronchial epithelial dose rate to average lung dose of 5 under the stated conditions of exposure.

However, the translation to man has remained a very perplexing issue. The tumors seemed to be associated with the larger bronchi. In general terms, the dose to this region was higher than the lung average, but the quantitative details did not come out closely enough to satisfy those who expected biology to behave like physics.

There were also such complications as: At what depth below the surface of the bronchus do the sensitive (critical) cells lie? What is the role of the mucus

layer and of various factors such as cigarette smoking, dustiness of the air, presence of ore dust, diesel smoke, and so forth?

Meanwhile, Stannard (1958) proposed that the lung should be regarded as a moderately, but not extremely, radiosensitive tissue, e.g., not as radiosensitive as the hematopoietic tissue. This view has held with time, with the possible exception of the effects of plutonium (see chapter 9). It implies that we should not be surprised at effective doses somewhat higher than for phenomena such as leukocyte counts.

The next steps were to focus down on the relationship between absorbed dose and the incidence of carcinoma and between radioisotope concentration in inhaled air and the dose to the critical tissue. The epidemiologic findings were, as always, slow to accumulate. Yet something needed to be done. Furthermore, the dosimetry side of the equation needed solving to put beside the incidence figures when they did become firm.

The basic steps to arrive at the contribution to total dose of each of the daughter products, whether preformed or formed in vivo, and of radon itself, are individually simple. However, in the aggregate, as many a health physicist has discovered, they present a formidable task. Fortunately, the lucid review of the whole procedure by Evans in his paper, "Engineer's Guide to the Elementary Behavior of Radon Daughters," gives all the physical principles, even how to make calculations from samples collected on filter paper. We need to go no further here than refer the reader to this summary (Evans 1969). Actual values of lung dose will be apparent when we consider the epidemiology.

How to apply the information to the biological system was not so directly answered. It has involved an orgy of modeling; necessary, but frustrating. This activity will be considered in the next section.

C. Modeling

Probably some of the earliest lung models were stimulated by the radon problem. Failla (1942) proposed a simple model of the bronchus that was generalized for all radioactive gases of interest in the MED operations. Mitchell (1945) included the contribution of the decay products formed in the bronchus. Evans (1950) calculated doses using a similar model of a large bronchus, an air concentration of 3,000 pCi/l, and seventeen years as the average tumor induction time to get the total dose to the bronchus as 3,000 rem. However, it was the combination of modeling and experimental observations by Chamberlain and Dyson (1956) that elevated modeling to the position in this field that it still maintains.

Two excellent summaries of the dilemmas of radon lung dosimetry and modeling for dosimetry^(a) have been prepared by H. M. Parker. One (Parker 1966) was a research report prepared specifically for the Federal Radiation Council (via the NAS-NRC); the other was a paper presented in a workshop held by the Health Physics Society at Denver in 1968 (Parker 1969). Both give nearly all we need to know about the basis for the special problems of modeling for radon exposure. It is in the first paper that Parker divests himself of the pent-up frustrations almost inevitably associated with the minutiae of this field and quoted earlier in this chapter, "... far more is written about the subject

(a) General lung models will be reviewed in chapters 9 and 16.

than is known about the subject." The Parker papers added to the understanding of the subject.

Two rather typical models for tissue dose from radon and its daughters were detailed at the 1964 Hanford symposium, *Inhaled Particles and Gases*. Altshuler, Nelson, and Kuschner (1964) did calculations on distribution of activity by size for each nuclide, predicted alpha decay in the bronchial regions, did measurements of epithelial thickness, etc. Except for anatomical measurements, the exercise was entirely calculational.

The second is one prepared by Jacobi (1964) from West Germany. This considered ordinary unfiltered air. He concludes that ciliary transport is a critical factor in bringing activity to the upper respiratory tract and that the highest dose should be expected in the secondary to quaternary bronchi.

For both of these, the general pulmonary retention theories of Findeisen (1935) and their modification by Landahl (1950) were employed.

Many other modeling efforts followed, using stylized descriptions of the respiratory tract (e.g., Weibel 1963), diffusion from an air stream flowing through a cylindrical tube (Gormley and Kennedy 1948), and many variations on the model for a typical bronchus. The aerosol physicists played important roles in all of these efforts.

The modeling efforts have proceeded into the environmental field to consider urban air (Fisene and Harley 1974) and general environmental exposures (Harley and Pasternack 1981). It continues to be an active counterpart to the development of effects data from epidemiology (NCRP 1984a).

With variables as numerous as particle-size spectrum, daughter-product spectrum, free-ion versus attached fraction, physiological and anatomical variations, etc., there is room for many models and for many champions to appear favoring one model over another. While many of the modeling efforts have been purely by calculation, some have been accompanied by experimental checks. For example, the advent of special plastics has made possible remarkably detailed casts of human and animal lungs for checking the theoretical morphometry.

In some instances, the modeling seems to have become an end unto itself, with the biology of secondary interest. We will leave more details of modeling for the interested reader to follow in the references at the end of this chapter and the application of modeling to the working level (WL) concept at the end of the next section.

D. The Need for a New Measure—Genesis of the Working Level

The solution of the major dilemma about the role of radon daughters was scientifically satisfying and of major importance; but it also complicated the lives of those who had to measure exposure levels in the mines or around mills or mill-tailing dumps, or to evaluate exposures. The scientific unit of preference was clearly disintegrations per minute per unit of volume or curies per liter, but of what? The original standards were in terms of radon gas. This would no longer do. Yet, expression as so many picocuries per liter of each daughter was complex and time consuming; see for example Evans (1969) and the Tsivoglou method as detailed in his paper at the 1955 Atoms for Peace Conference (Tsivoglou 1956).

The atmosphere in the mines was almost never in full equilibrium with the daughters except in quiet, unused areas. Air movement caused by natural or artificial ventilation, the activities of ore movement, the size and quality of the

mineralized mass, and other factors^(a) could result in fractions of equilibrium from 0.1 to nearly unity.

It was suggested that an average fractional equilibrium of 0.5 might be used. However, measurements showed that this would not be a satisfactory solution. There was too much variation. Something better, yet simpler to manage than determinations of each daughter individually, was needed.

The rapid expansion of uranium mining in the U.S. Colorado Plateau region in the late 1940s and early 1950s led to requests for assistance in evaluating the mines. Among the first to respond were people from the U.S. Public Health Service (USPHS), along with some representatives of the New York and Grand Junction Operations Offices of AEC. Among the former was Mr. Duncan A. Holaday, an industrial hygiene engineer in the Public Health Service who essentially spent the rest of his career with the uranium miners and radon problems. There was little equipment or "know-how" for the first year or so, but by the summer of 1951 Holaday, Howard Ayer, and assistants had begun environmental surveys of the mines. They knew intuitively that it was alpha dose from the two polonium isotopes (see figure 3.1) that most needed to be measured. They took filter paper samples under widely varying conditions. They got help from the mine operators and state health department people. They slowly worked toward a standard set of measurements by taking readings of activity at twenty, sixty, and eighty minutes after cessation of sampling. This work was helped considerably by the assignment in 1952 of Ernest Tsivoglou, who interrupted his doctoral research being sponsored by the Public Health Service to come to the mines. In the winter months, they collared Howard Cousins, who had been assigned to the station at the time to work out a system. The ideas gradually coalesced into something known at the time as the "Cousin Method" (Holaday 1979). However, there was still no generally accepted approach.

Then came the Seven-State Uranium Mining Conference on Health Hazards held in Salt Lake City in February 1955 with 155 attendees. Here the seriousness of the potential health problems was becoming quite apparent, and the need for some operationally useful measure of potential biological damage from a given atmosphere in a given mine became overwhelmingly urgent (Seven-State Conference 1955).^(b)

(a) A useful summary (from Jammet and Pradel 1956) of the results of monitoring in French mines is as follows:

1. The concentrations found in uranium mines are very high and often exceed 10^{-10} c/l, even with substantial ventilation, of the order of 4 and 8 m³/sec.
2. The concentrations depend, not only on the size of the mineralized mass and its uranium content, but also on the nature and compactness of the rock.
3. The use of explosives to break down the ore releases an important fraction of the bound radon as the rock is broken to pieces. In the blast smoke, concentrations of 5×10^{-8} c/l were found.
4. In the unventilated galleries, radon accumulates in very high concentrations, and by diffusion pollutes the other galleries.
5. The water which circulates in the areas where there are lodes dissolves the radon formed in the cracks and releases it on contact with the air as it seeps down and drips in the galleries.
6. Apparently clean galleries contain substantial amounts of radon brought, either by diffusion through the earth, or carried in by the waters.

(b) Proceedings of this conference are difficult to obtain. This author is indebted to Dr. E. Tsivoglou, Atlanta, Georgia, for a complete copy. The conference was chaired by John Z. Bowers, the University of Utah dean (more in chapter 8).

It is said that the conferees were determined to set some sort of standard if at all possible. Two scientific papers offered suggestions. One by Roy Albert from the Division of Biology and Medicine of the AEC offered a suggestion under the rubric, "the thinking has been (that) 100 micromicrocuries per liter is not a bad number for radon in equilibrium with its daughters." Further along, Paul F. Woolrich (USPHS) stated that "ventilation in the working areas should keep radon degradation products at less than 300 $\mu\text{Ci}/\text{l}$ (total daughters)." Neither man was in a position to do more than offer suggestions, since neither the AEC nor the Public Health Service was legally empowered to control exposure in the mines. But the anxious operators fixed upon these numbers. Even though the minutes of the meeting show no formal action, it seems to be generally agreed that the conference members went home with these figures in mind as a tentative standard.^(a)

Actually this had not solved the problem of mixtures that were not in equilibrium, and most of the mine atmospheres were not equilibrium mixtures. It required one more step to devise a unit that would be useful for control of ventilation and rough estimation of hazard. The latent solution was buried in the cogitations of those present.

In the USPHS Publication 494 (Holaday et al. 1957) a very complete and useful set of tolerance calculations for radon and daughters concludes with the following:

Comment - Sufficient biologic data are not available to determine finally a maximum permissible concentration for radon daughter products. It is hoped that studies now in progress will furnish these data. *In the interim, a working level of 1.3×10^5 MeV of potential alpha energy per liter is suggested for radon daughter products (RaA, RaB, and RaC).* This amount of energy will be released by the decay of 100 micromicrocuries of each of these elements through RaC'. On the basis of present information, the level appears to be reasonably safe and not unduly restrictive to mining operations. (Holaday et al. 1957, p. 20; emphasis added)

This is the first appearance in official print of the "working level" concept. It was obviously not its first use informally. Indeed, the enormously useful chronology of uranium mining health protection activities prepared by C. G. Stewart (1971) states that the Industrial Commission of Utah promulgated a regulation a year earlier that "mine air should not exceed 300 pCi/l of radon daughters (1WL)." (Emphasis added.)

Persistent pressure on Duncan Holaday in personal interview failed to elicit an admission that the term "working level" was of his coinage; but neither did it elicit a denial. Probably it was one of those ideas that grew by consensus.

The interview (Holaday 1979) did elicit emphasis on the interim nature of the idea and that it was not in any way to be considered a standard for planning, etc., but only for operators to use to gauge the effectiveness of their controls.

The working level was defined as any combination of radon daughter products that would produce 1.3×10^5 MeV of alpha-particle energy. This derives from the alpha particle contributions of RaA and RaC' since the beta energies of RaB and RaC are of little importance. Besides, they decay shortly (within minutes or hours) to RaC', which then delivers its whopping 7.68 MeV alpha ray. Thus, the figure refers strictly to potential alpha energy and should be worded as "any combination of the short-lived decay products of radon in 1 l of air that will result in the ultimate emission of 1.3×10^5 MeV of alpha-ray energy."

(a) Note that 100 $\mu\text{Ci}/\text{l}$ of radon in equilibrium with its daughter products is roughly equivalent to 300 $\mu\text{Ci}/\text{l}$ of radon daughters expressed as "total daughters."

Table 3.5 summarizes the definition. Note well that the definition holds for any combination of daughters producing that total amount of alpha energy. Note especially that radon is given no weight in defining the working level.

TABLE 3.5. Definition of the "Working Level" (WL) Unit

Nuclide	α -Ray Energy (MeV)	Half-Period	No. of Atoms per 100 pCi	Ultimate α -Ray Energy per Atom (MeV)	Total Ultimate α -Ray Energy (MeV/100 pCi)	Fraction of Total α -Energy
Rn (Rn^{222})	5.49	3.82 days	1.77×10^6	excluded	none	none
RaA (Po^{218})	6.00	3.05 min	977	$6.00 + 7.68$	0.134×10^5	0.10
RaB (Pb^{214})	0	26.8 min	8580	7.68	0.659×10^5	0.52
RaC (Bi^{214})	0	19.7 min	6310	7.68	0.485×10^5	0.38
RaC' (Po^{214})	7.68	10^{-6} min	0.0008	7.68	0.000×10^5	0.00
Total					1.278×10^5	1.00
Call it					1.3×10^5	

Source: Reset from Evans 1969. Reprinted with permission of Pergamon Press, Ltd., Elmsford, New York, copyright 1969.

Note: Even though RaB and RaC do not contribute alpha energies themselves, they decay to RaC' and thus add to the total ultimate alpha-ray energy. Also, there are enough more of them in 100 pCi of an equilibrium mixture because of their longer half-period to result in their contributing a major portion (0.90) of the total alpha energy.

The working level idea took well in the United States and Canada.^(a) Soon records were being kept as products of working levels and time, such as working level months (WLM), even in working level years (WLY). An enormous effort was put into instruments that would give more rapid readings than the ponderous filter-paper-sample technique. The merit of calling attention to the original alpha-emitting decay products and the convenience of having only one entity to measure won the working level popularity far beyond its true validity as a unit.

Many authors have pointed out—indeed measured—the radiation dose equivalent to 1 WL under varied conditions. Obviously, the rad dose to pertinent tissues in the respiratory tract associated with 1 WLM will vary with the fraction of equilibrium, altitude, temperature, breathing pattern, etc. The conversion factors of rad/WLM can range from as low as 0.2 to as high as 10. But mine conditions seldom vary as widely as these factors would indicate since other items were included besides fraction of equilibrium. A figure of about 7 rad per WLM with a range ± 5 was used for a while (Stannard 1973), but 0.4 to 0.8 rad = 1 WLM is the average used in the BEIR III report (BEIR III 1980). This figure is subject to a wide range (Morken 1969; Pasternack and Harley 1971).

The reviews of Evans and Parker, already cited, address the usefulness and the problems of the working level concept. The polemic is still going on as seen in a recent report from the National Council on Radiation Protection and Measurements (NCRP 1984a).

A further source of complexity is, of course, the fraction of *unattached* radon decay products. This is not included in the working level calculation. Since

(a) Never mentioned in the reasons for enthusiasm on the part of the operators is the fact that the WL actually allows levels that are a factor of ten higher than the original standard of 10 pCi/l, assuming that a limit of 1 WL was applied.

these are highly reactive, they would "plate out" in the lungs with greater efficiency than atoms attached to a vector aerosol. Should they be measured separately? Mercer (1975) has analyzed the significance of this fraction and presented data for the unattached fractions of radon decay products in over sixty samples of mine air. While some approached 25% for RaA (even 55% in one case) most were small. Indeed, Mercer and Stowe (1971) discouraged routine measurements of the unattached fraction. Yet, there are those who place special significance on this fraction and view its omission from the working level definition and measurements as serious. This is another area where the research is incomplete and the unit insecure.

The interim nature of the USPHS proposal was seriously compromised by adoption of the working level as a *formal standard* by the American Standards Association. They gave it the force of a maximum permissible concentration. Since then regulators have been prone to use not only the WL and the WLM, but cumulative working level months (CWLM) in regulating U.S. and Canadian operations.

The new unit solved some important practical problems; but the problems of dosimetry and radiobiology were obviously not fully solved. Furthermore, in a sense, having the unit seems to have deterred necessary basic research into both the radiobiology and dosimetry necessary to arrive at the true dose associated with a given set of conditions measured in working level month units. Unfortunately, no really attractive substitute for the working level has been worked out except the old laborious calculation for each daughter. As Parker (1966) stated, "the needed radiation parameters will not be known until the relevant biological target has been more clearly specified." While he urged de-emphasizing the working level concept, it has flourished ever since and will probably continue for expression of radon exposures until the true cause-effect, dose-response relationship is worked out. Nearly all expressions of dose to individuals exposed to radon are now couched in terms of the working level. This includes even the United Nations' recent reports (UNSCEAR 1977, 1982) and recent International Commission on Radiological Protection (ICRP) reports on radon (ICRP 1977, 1981).

Thus, the idea born of a practical measurement problem has become almost an official unit. It is doubtful if a unit with such a range of conversion factors could ever become official in the world of scientific standards, but it has come far—too far—from its original interim status.^(a)

(a) A clear indication of the dilemmas we still face and an instance of applying modeling techniques to the working level concept has come from the group at Harvard whose work on inhalation problems we will meet in chapter 9. Desrosiers, Kennedy, and Little (1978) attacked the problem by reasoning from information from experiments using the Syrian Golden hamster expressed in working level year to human exposures. The abstract of this important paper is given below:

Abstract—A detailed morphometric description of the dimensions of airways, the branching patterns, and the epithelial cell frequencies in the respiratory tract of the Syrian golden hamster has been completed. We used these data to construct a mathematical model of the deposition of inhaled particles and their subsequent regional translocation during extracellular lung clearance. The number of disintegrations per year was calculated for ^{218}Po and ^{214}Po in each airway group using reference radioactive atmospheres. Disintegrations were converted to absorbed dose using the depth-dose distribution in a cylindrical tissue annulus for each alpha particle energy. The resulting doses show a significant difference between the types of cells and locations receiving maximum exposure when the model of the hamster lung was

E. Methods of Measurement^(a)

Although general methods for measurements of radioactivity are described in chapter 17 and those intended especially for field application in chapter 18, we should pause briefly to look at those for radon and its daughter products. Fortunately, a recent ICRP report (ICRP 1977) contains a succinct summary. A number of U.S. laboratories were actively engaged.

The techniques fall into four categories: (1) radon concentration, (2) radon daughters, (3) unattached radon daughters, and (4) radon and radium in water. Excerpts and paraphrasing from the subject ICRP report should suffice to illustrate the principles.

1. Radon Concentration

Routine measurements of radon concentrations in mines are usually made by taking samples in the mine for measurements at ground level. The samples are taken in scintillation flasks or evacuated metal containers. Activated charcoal is also used as a sample collector. Sometimes a technique called the two-filter method is used, and in this case measurements in the mine are preferred (ICRP 1977, p. 18).

The two-filter method consists of drawing air through a pipe fitted at both ends with filters for radon daughters. Radon daughters in the incoming air are trapped by the first filter; the daughters trapped by the second filter are those formed during the passage of the radon between the first and second—the radon daughter activity at the second filter is proportional to the radon concentration (ICRP 1977, p. 19).

2. Radon Daughters

All methods involve collecting an air sample on filter paper for a given time at a known flow rate. Variations are in the methods of counting, the times the counts are made, and other details. The Tsivoglou method (see page 22 of ICRP 1977 and Holmgren 1974) measures the individual concentrations of RaA, RaB, and RaC in air.

3. Unattached Radon Daughters

Unattached radon daughters can be separated in the field by collection on a wire screen. Mesh size and sampling velocity must be worked out carefully.

compared to current models of the human respiratory tract. The dose to basal cells in the subsegmental bronchi is 0.4-1.6 rad per working level year (WLY). The mean dose to basal cells is 2-3 rad per WLY. Peripheral basal cells may receive doses approximately equal to doses received by basal cells in the central airways. Moreover, Clara cells in the terminal bronchioles may also receive 2-3 rad per WLY. Since Clara cells have been implicated in hamster lung carcinogenesis, the dose to these differentiated cells may be relevant to inducing tumors. In contrast, models of the human lung suggest that the highest dose to all types of cells is in the higher airways (subsegmental bronchi) and that the cancer-related dose is 3-20 rad per WLY for identical ^{222}Rn -laden atmospheres. Although these results are subject to the limitations inherent in the mathematical modeling of biological phenomena, they indicate that the frequency, and morphology of ^{222}Rn -induced lung cancer in hamsters may not be a straightforward indication of human response when exposures are expressed in WLY. (Desrosiers, Kennedy, and Little 1978).

(a) There is considerably more detail on measurement techniques in the recent special issue of *Health Physics* edited by Nero and Lowder (1983).

4. Radon and Radium in Water

For radon and radium in water, samples are taken at the point of entrance of the water into the mine (*not* from pools, the floor, or other sites where radon loss and/or contamination can occur). The whole bottle of collected water can be placed on a NaI crystal, or the radon can be transferred by the passage of air into a measuring chamber. These determinations are better made away from the mine itself and using conventional laboratory techniques.

VI. The Epidemiologic Studies in the Postwar Era

We have already summarized the new populations exposed occupationally to radon that became available for study in the post-World-War-II era. In this section, we will review briefly the genesis and results of epidemiologic studies as they now stand. Since there are already numerous reviews of the facts and their interpretation, emphasis will be placed here on the historical development of the work, particularly in the United States.

It was once the hope that the miner populations might produce results that could stand beside the ^{226}Ra , ^{228}Ra , and the ^{224}Ra studies described in chapter 1. That hope is fast fading. The conditions of exposure are so varied and so difficult to pin down that despite the best efforts of all concerned, we will probably never have as solid an indication of dose as we do for the radium cases. There is, of course, no residual body burden of the primary nuclides to measure, which throws the burden on in-situ measurements of exposure or assay of the long-term decay products either in the body or excreted. Efforts have been made to use the ^{210}Pb content of bone or its excretion (Bell and Gilliland 1964; Holtzman 1970) or, better, the urinary excretion of ^{210}Po (Sultzner and Hursh 1954; Djurić et al. 1964) to estimate the radiation dose retrospectively. There is clearly enough polonium excreted to measure conveniently in many miners with moderate to high exposures; but the connection to lung dose is a tortuous process.^(a) Another reason we cannot expect much more than we now have is that exposures have been greatly reduced (fortunately) by the institution of control measures. Nevertheless, the subject is of paramount importance in terms of numbers of exposed individuals and incidence of effects. A review is essential to any history of radioactivity and health.

A. The U.S. Uranium Miners

1. Assembling the Data

The study of the U.S. uranium miners has centered, in terms of manpower, in the U.S. Public Health Service, Division of Occupational Health. This Division had assistance from other sectors of the Public Health Service (including the National Institutes of Health) from AEC laboratories (notably the Health and Safety Laboratory in New York and the University of Rochester Atomic Energy Project) plus close collaboration with the states and the mine and mill operators. Geographically it has centered in the Colorado Plateau. The nearest thing to a

(a) Quite recently, European investigators have tried relating the ^{210}Pb content of teeth to exposure to radon and radon daughters (Clemente et al. 1984).

single center for the activity has been Salt Lake City, with Grand Junction an accessory center.

The genesis of the study is best told in the words of Duncan A. Holaday, who had an important part in every technical study, except the purely medical evaluations, and who traversed, personally, a substantial portion of this wild and beautiful area.

The following excerpt from Holaday's review in Volume I of the IAEA symposium is a good way to start:

Early in 1949, after the uranium-mining industry began to expand in the State of Colorado, the Public Health Service advised the Executive Secretary of the Colorado Department of Health that there were potential health hazards associated with the mining of uranium ores. Following a preliminary investigation, the Department of Health, the Industrial Commission, and the Bureau of Mines of the State of Colorado, and several of the larger uranium mining companies, requested the Division of Occupational Health of the United States Public Health Service to conduct a study of the potential health hazards associated with the mining and milling of uranium ores.

In the United States of America legal responsibility for protecting the health of workers is a function of the various states. The role of the Public Health Service in such matters is limited to research, including defining the problem and developing standards and control methods. The application of this knowledge is then a responsibility of the states concerned.

While negotiations with the State of Colorado were underway, limited study of the health problems in the uranium mines located on the Navajo Indian reservation of Arizona was conducted by the U.S. Public Health Service.^(a) This study indicated that the miners were exposed to external radiation, radon and a high silica dust containing an undetermined amount of radioactive elements. Additionally, it appeared that the vanadium and uranium contained in the dust were of toxicologic importance and that the matter of internal radiation due to the inhalation of radioactive dust also should be considered.

Concurrently, a review was made of the European experience and the literature was reviewed for contributory information. It was concluded that the health study should consist of two correlated phases: a medical study and an environmental investigation. Although medical examinations probably would not be immediately productive in uncovering pathologic changes because of the limited exposure period of the uranium miners, it was felt that the examinations should be given to establish rapport with the miners and the mining companies and to obtain baseline data regarding the mining population. Medical examinations of the miners and mill workers were performed during the summers of 1950 and 1951, during which time 1117 persons were examined with essentially negative findings. In 1953, it was decided that medical examinations be given on a triennial basis, with major emphasis on careful follow-up of active and inactive miners. . . . Uranium-producing mills were included in the original study concept. However, when it was determined that the mills were within the purview of the Atomic Energy Commission's regulations, the study was limited to the mining industry. (Holaday and Doyle 1964, references deleted)

From miscellaneous sources in Mr. Holaday's and this author's files, we can present the following:

1. When the PHS Division of Occupational Health was designated to assist Colorado in 1949, they had two survey meters for measuring external

(a) The U.S. Bureau of Mines is also stated to have surveyed mines on the Navajo reservation in early November 1949.

radiation; no equipment or competence for making radon, uranium, or radium measurements; a limited staff and no funds for such a study. One man was assigned by the PHS. Dr. Cleere, Colorado Department of Health, set up an advisory committee to consider uranium mining problems.

2. In December 1949, a grant application from the state of Colorado to the National Cancer Institute brought twenty-five thousand dollars for environmental and medical studies. The radon samples were sent to the National Bureau of Standards for measurement, uranium and radium in atmospheric samples were sent to the Naval Radiological Defense Laboratory, and the Los Alamos Laboratory did urine analyses.
3. In 1950, actual medical field work was started, but this was at the Durango Mill of the Vanadium Corporation of America. Later, workers from other mills were examined, and it was proposed that miners be brought to the mills for examination.
4. In December 1950, it was the consensus of all concerned that exposures to radioactive dust and gas in the mines were high enough to be of real concern. No reports were published, however. Financial help was sought from the AEC.
5. In 1951, the primary medical effort was expended on miners, and a new grant was obtained from the NCI.
6. Also in 1951, environmental measurements in nonuranium hard-rock mines indicated lower but still significant amounts of radioactivity therein.
7. In 1952, the state agencies and mine operators were urged to institute control measures to reduce exposures. AEC was asked for substantial financial help. (They had already loaned equipment from the New York office through Drs. John Harley and Merrill Eisenbud.) The Division of Biology and Medicine of AEC provided twenty-five thousand dollars. This, together with the PHS money, enabled a crew of six men to survey 159 mines during the summer. AEC also started surveys in Commission-leased uranium mines.
8. No medical examinations were done during the 1952 field season. An unpublished interim report of fifty mines and eight mills was prepared within PHS.
9. Medical examinations were resumed in 1953, with primary emphasis on the miners.
10. The epidemiologic phase became the responsibility of the NCI in 1953, leaving the Division of Occupational Health (DOH) primarily responsible for the environmental work.
11. In summer 1953, the Utah State Health Department surveyed all the operating mines in the state. Other states were much less well covered. They reported radon concentrations from 0 to 2,100 pCi/l in the mines, with most of the samples in the 500-pCi/l range.
12. In 1954, the epidemiologic team became a discrete entity. Also, with the help of the Grand Junction Office of AEC, teams were assembled to do a much more sophisticated type of survey. They used x-ray trucks, trailers where examinations could be made and hematology could be done, plus support equipment such as water tanks, generators, etc. Also in 1954, the revised Atomic Energy Act gave AEC control over material once it was removed from the mine.

13. In 1955, Utah issued regulations for control, and the standard for atmospheric concentrations was that referred to in section V of this chapter. Colorado prescribed 100 pCi/l for each of the alpha decay products. Also, better follow-up procedures for the medical study group were established, and a census of all uranium miners was developed. The work for this was carried on largely in 1956.
14. In 1956, both the environmental and medical surveys continued. However, the Bureau of the Budget stated that it did not approve of federal funds being spent on the uranium study, and the work was limited to assisting state agencies on request. AEC presented the first results of surveys of thirty-five Commission-leased mines. They were from two to eighteen times above the working level.
15. In 1957, an extensive medical survey was conducted with the same *dramatis personae*, except that Dr. Victor Archer replaced Dr. Eagan in charge of the medical field work. The census was combined with the medical study. How the negative attitude of the Bureau of the Budget was reversed or circumvented is not set down in any of the materials available to this author. No publications were released.
16. In 1958, it became apparent that four new deaths from lung cancer had occurred in the worker population. Despite this, control of the mine atmospheres was still quite unsatisfactory. None of the state mine inspectors felt they had authority or that the data were convincing enough to require the expensive and awkward controls needed. They did what they could by "education and exhortation."
17. A third general medical survey was conducted in 1960. The data began to be subjected to in-depth analysis.
18. During several meetings in 1961, many company representatives expressed disbelief in the existence of a medical problem, but the reputation of the U.S. Public Health Service never to "cry wolf" and never to have to retract a considered opinion seems to have impressed many.
19. After the "Governors' Conference" in 1961, many areas of some mines were caused to be shut down (Governors' Conference 1961).
20. As a result of Dr. Saccomanno's work at Grand Junction showing the miners' cancer cells were cytologically predominantly of the "oat cell" (i.e., small cell) type, an annual sputum cytology program was instituted about 1961.^(a)
21. Despite niggardly appropriations from Congress, the medical and environmental field work continued through 1963, when the medical phases were severely curtailed. This was partly because the levels of exposure were now reduced and it was a matter of waiting out the latent period for cancer induction, partly because the effort and funds needed to be concentrated on data analysis and environmental surveys.
22. The census/sputum-cytology program was continued into 1964. The number of cancer cases began to increase rapidly.

The laboratories participating have already been named. Personnel waxed and waned since much of the work was done during the summer season by

(a) This characteristic of the cancer cells undoubtedly existed for a time, but the consensus now is that the undifferentiated small cell type is not universal or unique. Saccomanno shares this view (footnote b, page 153).

temporary assignments, and there was the usual shuffling of PHS officers characteristic of a semimilitary organization. Some names need special notice, however. For the medical surveys we should note:

Public Health Service: V. Archer, W. C. Cooper, J. W. Egan, E. Harris, W. C. Hueper, F. E. Lundin, H. Magnuson, R. W. Miller, J. K. Wagoner, and M. R. Zvon.

Others: Grand Junction, Colorado: G. Saccomanno, St. Mary's Hospital and Veterans Administration Hospital. Grants, New Mexico: M. A. Connell, Grants Clinic, Medical Consultant to several companies. University of Rochester School of Medicine and Dentistry: A group led by M. L. Ingram spent one summer doing medical examinations and hematological determinations on miners throughout a large area. Results have not been identified individually.

For the environmental surveys we note especially:

Public Health Service: S. C. Black, R. L. Blanchard, H. Doyle, M. Haij, C. Jensen, H. Kusnetz, P. A. Lawrence, and E. C. Tsivoglou.

Others: AEC: W. F. Bale, G. M. Dunning, M. Eisenbud, and J. Harley. Colorado State University: A. Dahl, K. Schiager, and others.

In addition, a number of personnel from agencies of the states of Colorado, Utah, and New Mexico took active parts.

Ubiquitous to all phases was D. A. Holaday, whom we should regard as "Mr. Radon" for the U.S. efforts.^(a) His review in a 1974 National Institute for Occupational Safety and Health (NIOSH) document (Holaday 1974) gives a clear overview of the efforts and of Holaday's comprehensive grasp of the field.

2. Results of the U.S. Epidemiologic Study

Like all epidemiologic studies, definitive results came slowly. Yet, it must have been apparent even from the early returns, the measured environmental levels, and the experience in Schneeberg and Jachymov, that numerous American underground miners were slated to die of lung cancer.

An early report of the PHS work appeared as two papers in the International Atomic Energy Agency (IAEA) symposium already cited. One concerned non-fatal effects (Archer et al. 1964). This was limited to the respiratory system. The other report gave gross mortality patterns for miners and millers, 1950 through 1962 (Wagoner et al. 1964). There was an increase in mortality in the miner group, but due primarily to accidents. The authors comment, however, that there was a tenfold excess in incidence of respiratory cancer among the miners with long-term underground experience.

There followed an extremely active period in review of the American data. The Federal Radiation Council (FRC) gathered opinions from all quarters on the PHS data and their analysis. This resulted in a preliminary FRC report, which was issued without recommendations. The Joint Committee on Atomic Energy (JCAE) called a series of hearings on the uranium miner problem in 1967 (JCAE 1967). The FRC preliminary report was released for discussion at these hearings. The PHS brought in its most recent data and analyses. There were questions

(a) It is fitting that Mr. Holaday was the first recipient of the distinguished achievement award of the Health Physics Society at its meeting in June 1968.

raised about these,^(a) and an interdepartmental committee was set up to resolve the outstanding questions and come up with recommendations. The FRC reviewed its preliminary report and issued a revised version in September 1967 (FRC 1967).

Because of the growing political overtones in the uranium miner saga (see section VI B), the Federal Radiation Council requested assistance from a blue-ribbon advisory committee of the National Academy of Sciences-National Research Council chaired by Cyril Comar (the first of two such committees) (NAS-NRC 1968). They concluded that the chief problem at the low exposure levels was allocation of workers to categories of exposure. After all, the measurements were only spot checks and were always subject to local conditions. They held that the increased cancer incidence above 400 CWLM was clearly significant and that an increase between 100 and 400 CWLM was not an artifact of the data, although causation was not so clear. They concluded that cigarette smokers were particularly susceptible.

Interim recommendations were made for limiting mine exposures, and plans were made for lowering the levels on a predetermined schedule. However, the schedule had to be changed and delayed. The JCAE called more hearings in 1969 (JCAE 1969).

The interdepartmental committee, which now had the name "The Inter-agency Uranium Mining Radiation Review Group" (IUMRRG), issued a series of reports on all aspects of the problem from health effects to economic factors. Its final report was reproduced in the *Federal Register* in 1971 (*Federal Register* 1971). Also, a second NAS-NRC report was sent to the IUMRRG (NAS-NRC 1971). Nearly everyone with experience in radon problems was called upon to testify or sit on one of the committees.

During the middle of this period of examination and re-examination of the data, Willard Wirtz, then Secretary of Labor, invoked the Walsh-Healy Act and on May 5, 1967, arbitrarily set a level considerably lower than any of those under consideration: 0.3 WL. There was no scientific evidence to support such a drastic decrease, nor was it "reasonably achievable" at the time, but it had to be probed along with the technology. The motivation was undoubtedly the Secretary's desire to protect the miners as fully as possible, impatience with the haggling of the scientists and technical people in general, and an understandable emotional ingredient in the fact the Secretary had lost two family members to cancer. While technically not attainable at the time, the setting of this low level undoubtedly influenced the process of gradually decreasing the official occupational exposure standards with 1 WL accepted in principle by FRC in July 1967.

A moderately complete new report from the Public Health Service was published in 1971 as a joint monograph from the National Institute for Occupational Safety and Health and the National Institute of Environmental Health Sciences (NIEHS) (Lundin, Wagoner, and Archer 1971). This showed a total of 437 deaths compared with 277 expected in white and 72 deaths compared with 90 expected in nonwhite underground miners. Most, but not all, were caused by malignant neoplasms.

There was no question in this report of there being a causal association between lung cancer incidence in the mines and exposure from 400 up

(a) It should be recalled that the uranium miner study was not originally set up as a true epidemiologic effort.

to 1,000 CWLM or more. It was also clear that there was a statistically significant increase between 100 and 400 CWLM contributed substantially, but perhaps not entirely, by radon daughter exposures. Overall, the lung cancer incidence for the period 1950 to 1968 was about six times that of nonminers.

Problems still resided in the studies, however. The significance of exposures at levels below 100 CWLM could not be established with the data in hand. Yet, it was at these lower levels that most interest centered, because of the strong desire to establish firm standards. Also, the role of cigarette smoking was difficult to work out. For a while, it seemed as though no miner who did not smoke got lung cancer. But this seems to have been partly a trick of the data. As explained by Holaday (1979), taking a simple answer to the question, "Do you smoke cigarettes?" was not enough. It needed to be followed by, "How many?" Many of the Navajos smoked almost not at all, but would answer yes to the simple question since having money to buy cigarettes was considered a status symbol. The smoking might amount to one or two cigarettes in town on a Saturday night!^(a) Again, note the problems of record-keeping and importance of an intimate knowledge of the situation at hand for the conduct of retrospective epidemiology. Cross et al. (1974, section 2.4) give a full and readable summary of the activities of this period and their impact on the final standards set. Also in 1974, Holaday produced his summary report for NIOSH (Holaday 1974). We will defer to them for further details.

As of 1981, the U.S. Uranium Miner Study consisted of medical studies of 3,366 white men and 780 nonwhite men (mostly Navajo Indians) who had at least one month of underground employment in 1963 or before. About 43,000 radon daughter measurements were made, mostly between 1951 and 1969, after which levels became too low to continue to figure in the study. Lung cancers are now above expectation in all exposure categories above 60 WLM. Exposures extended from less than 100 to nearly 10,000 WLM (Archer, Wagoner, and Lundin 1973).

A linear relationship between dose in working level months and cancer incidence has been plotted by many, but the true shape of the dose-response curve remains for future work to ascertain. We can expect new summaries in reports now in preparation, but these are not yet history.

The interpretations have been extended to induction rates (UNSCEAR 1977) and to risk estimates (Evans et al. 1981; BEIR III 1980; and others). Any further discussion of these matters would carry us beyond our time and scope.^(b)

It appears that the U.S. epidemiology study is now one of the most complete and secure of all we have. It represents an enormous effort under trying field conditions. While the precision of such results can never be expected to match those of controlled laboratory experiments, they have the advantage of being composed of data on man exposed in "real-world" situations. Also, they show what can be done by dedicated workers on relatively small budgets.

(a) Inquiry to Dr. Saccomanno at the NCRP annual meeting in March 1988 negates the importance of this point. In his experience, most of the miners who smoked were heavy smokers.

(b) Incidentally, in some categories it appears now that cigarette smoking may lower incidence of bronchiolar carcinoma because of the increased thickness of the mucus layer. Also the predominance of small cell types in the lung cancers seems to have disappeared. In fact, other cell types appear to be taking over. It is the opinion of Saccomanno (1981) and Saccomanno et al. (1981) that the types being seen now are so characteristic of cancers induced by cigarette smoking that it may indicate that the new cases are only tenuously connected to radiation exposure.

About the time of the nominal cutoff for this historical review, the field opened wide, as we will see presently.^(a)

B. Why Did it Happen Here?

When it became apparent in the 1960s, and beyond, that the United States would have several hundred cancer deaths among uranium miners, and this despite the well-established experiences in prewar Germany and Czechoslovakia, many officials, agencies, individuals, and organizations indulged in the usual practice of "Monday morning quarterbacking." Special vituperation was vented upon the AEC for not taking a firmer hand, or indeed taking over the situation, early in the 1950s. The stark contrast between protection of uranium miners and that afforded other workers in the atomic energy industry aggravated such thinking.^(b)

Few seem to realize that what was done, as recounted in the previous section, was only following the general pattern of the day of all federal relationships to industry. The states had the responsibility for protection of their workers, and they guarded it jealously. Always the Public Health Service provided advice and information *when asked*, assistance *if specifically requested*; but they never made an attempt to take over or even give the appearance of doing so. Only on federal lands could agencies such as the Bureau of Mines exert control of mining operations.

(a) In 1979, the Colorado School of Mines sponsored a conference/workshop, Lung Cancer Epidemiology, which included updating papers on effects of exposures to low levels of radon and discussion of factors involved in exposure-response relationships (see, for example, Archer 1979). In 1980, a specialist meeting, The Assessment of Radon and Daughter Exposure and Related Biological Effects, was held near Rome, Italy. The proceedings were edited by Clemente et al. and were published in 1982. Several pertinent updates of the subject of this section were included, e.g., Cross et al. (1982); Fisher (1982); and Steinhäusler, Pohl, and Hofmann (1982). In 1981, the Committee on Indoor Pollutants of the Board of Toxicology and Environmental Health Hazards of the U.S. NAS-NRC produced a report that summarized information on dose-response calculations (NAS-NRC 1981). Also in 1981, an international conference was held at the Colorado School of Mines, Golden, Colorado, on radiation hazards in mining. It was sponsored by the American Institute of Mining, Metallurgical, and Petroleum Engineers (Gomez 1981) and contained thirty-six identifiable technical sessions, several planning sessions, and luncheon addresses. The sponsors stated that this was the first international convocation of scientists, engineers, and various health specialists that concentrated on *ongoing research throughout the world*. There was considerable discussion of epidemiology, standards, and methodology. Perspective on the cancer problem is given by Archer (1981).

In the even more recent past, Bair (1986) included much germane discussion on radon problems in his general review of experimental carcinogenesis of the respiratory tract; Whittemore and McMillan (1983), working at Stanford under a PHS grant, reappraised the lung cancer mortality statistics among U.S. uranium miners and suggested a multiplicative function; Cross (1984) produced a complete review of animal data on radon inhalation; and finally, two NCRP reports were issued (NCRP 1984a, b). It is obvious that the subject remains extremely active. The emphasis has shifted, however, to nonoccupational exposure. We will review this new emphasis briefly in a subsequent section of this chapter and in the environmental chapters.

(b) A useful and authoritative review of many of the considerations in this section can be found in testimony presented by Merrill Eisenbud before the Subcommittee on Health and Scientific Research of the U.S. Senate in June 1979 (U.S. Congress 1979).

The Atomic Energy Act gave AEC jurisdiction over many processes and areas which, had the material been for nonnuclear use, would have been completely a states' rights proposition. However, as the historical notes of the previous section show, this jurisdiction did not extend to mining. Before 1954, it did not even go as far back as "material once removed from the ground." Legal counsel of the AEC repeatedly advised the Commission's officers and personnel to refrain from overstepping the statutes, and to stay out of the mines. They were under PHS cognizance if any federal participation was needed!

We have seen that AEC provided funds, equipment, and personnel even if perhaps not in the volume really needed. We have also seen that the federal establishment broadly was loath to give proper financial support when it was most needed—in the early years. We also know that the operators, faced with meeting contracts, were not anxious for a spate of new regulations and increased expenses and delays in production.

Other factors are more or less idiosyncratic to the uranium mining operation. Ventilation was the best answer. But not only did it cost in power and equipment, many of the mines had only portable generators, and long supply lines for fuel were needed. In winter, the necessary ventilation produced blasts of cold outside air, which made the workers want to tie off the inlet pipes. Sometimes they did. Inducing personnel to wear respirators has always been a problem in industrial operations. In the uranium mines, especially the small ones, respirators were a lost cause in the early years. Many of the smaller mines would have had to close since they could not afford the expense of ventilation equipment. At that time, uranium ore was needed urgently, for the "cold war" was blowing hotter than most realized. The AEC was on the horns of a dilemma with regard to reducing the flow of ore versus enforcing controls or trying to do so.

All these factors, plus the continued skepticism of many as to the reality of the problem, resulted in a very long period of what now appears to be culpable inaction, but what was at the time a result of opposing forces and inertia.

There are many who hold that the AEC was all too willing to accept the dictum of their legal counsel and stay away from the uranium miner area, except for lending assistance. The AEC, as will be seen in chapter 12, already had its hands full with the fallout ruckus. Also, any overt intervention might strain relations with the PHS, which clearly had the statutory priority. As an employee of a related division of the PHS during some of the years just prior to the expansion of uranium mining, this author can testify to the sanctity surrounding the PHS relations to the states. Perhaps the AEC could have been more aggressive. Only those in the seats of responsibility at the time can testify.

The real tragedy of the U.S. uranium miner saga is not that the AEC did or did not push people around, or even that the PHS and the federal Treasury were too parsimonious. It is that the lessons of Joachimsthal and Schneeberg had to be learned all over again. As soon as the radon levels were found to be equivalent to those in the European mines, the outcome was apparent, unless something was done and done quickly. Instead, we waited to prove that radon daughters could kill Americans as well as Europeans.

Does this mean that American science was callously disregarding the human suffering involved? Anyone who follows the tortuous process of establishing a scientific fact knows the answer to this question is negative. There were lingering doubts even about the European studies. The general health of the European miners, even in the 1920s and 1930s, was poor by Western standards of the late 1940s. Cofactors had not been eliminated from consideration, and they were

clearly potentially different in the two situations. Indeed, this possible complexity is not yet fully eliminated from consideration, nor will it ever be until we know cancer biology much more fully.^(a)

As Cross et al. (1974) point out, in retrospect, we had the data to set a standard of 6 WLM by the early 1950s. If we had done so, the number of lung cancer cases would have been considerably reduced. Unfortunately, we were not really sure of either causation or dose-response kinetics. Add to that the important financial considerations, the all-too-familiar ability of one generation to forget the lessons of an earlier one, and the jurisdictional problems already made clear in the capsule history above, and we can understand (but not condone) the delays in getting protective measures going.^(b) By the time the validity of the U.S. scientific results was established, the biological damage had been done. Let us hope our current problems with chemical pollutants in the environment do not have to go down this dreary path of repeating the past no matter what lessons it can teach.

Space prohibits recounting the numerous steps taken once the danger was fully appreciated. These can be seen in the JCAE hearings, FRC reports, numerous notices in the *Federal Register* (1967, 1968, 1970, 1971), and reports from the IUMRRG (final report in the 1971 *Federal Register* cited). For our purposes, it is worth noting how completely the situation changed from failure to act on recommendations from fully credible sources to an avalanche of demands for action and better (i.e., lower) standards. Agencies and individuals vied with each other for the position of savior (e.g., the Secretary of Labor and the Secretary of Health, Education and Welfare). Fortunately, the work of the PHS has been adequately, although not fully, recognized. It was, however, the FRC's work that, in this writer's opinion, really brought about the reversal of attitude. This does not seem to be generally appreciated. The coalescence of federal agencies in the council was the catalyst that got the reaction going^(c) in the early and middle 1960s.

C. Other Uranium Mines

The postwar study of the Czechoslovakian uranium miners was reviewed first by Horáček, (1969) and assembled in detail by Ševc, Kunz, and Plaček (1976); Kunz, Ševc, and Plaček, (1978); and Kunz et al. (1979) among others. There are problems in identifying how many miners were in the two major groups, those who

- (a) Remember how foolish the idea of fungi in the mines seemed as a contributing factor? Professor Dr. V. Wolf at Karlsruhe recently drew this author's attention to a paper by a microbiologist of the Laboratory ORL of the Czechoslovak Academy of Sciences (Kusák 1969) that describes the large number of fungal conidia inhaled by the miners and the balance of antimycotic and mycotic effects. Of special interest is the production under certain conditions of the potent biological carcinogen "Aflatoxin" by *Aspergillus flavus*, a frequent component of the fungal population. No proof exists that it takes part, but it could some of the time.
- (b) The atmosphere of the times played its part too. In the early 1950s, the United States was busy establishing a nuclear industry, both military and civilian. The public was fairly solidly behind the effort. People who advocated shutting down uranium mines because of not-yet-proven health hazards were likely to be viewed as subversive.
- (c) Several histories of radiation protection activities are now in preparation. It is assumed that further details on these matters, which are beyond the purview of this book, will appear in one or more of these.

started mining between January 1948 and December 1952, and those who started between January 1953 and December 1957. It appears that there are about twenty-five hundred persons in the first group and nineteen hundred in the second (NCRP 1984a). Excess lung cancers in the first group are 169 through 1973 (i.e., 212 observed versus 43 expected). The second group was exposed too recently to be used currently. The exposure categories range from 72 to 716 WLM. There were over 120,000 radon measurements made.

Risks calculated for this group are higher than those in the U.S. group by a factor of two to three. On the whole, the Czech study appears useful and comparable in reliability to the U.S. work (Evans et al. 1981). The difference in calculated risk may or may not be significant. No explanation is apparent.

The Canadian uranium miners contributed the third postwar group for epidemiologic study. Uranium mining began in Canada in 1954, with a peak of eleven thousand miners employed. However, duration of employment and exposure declined by 1965, and radon daughter measurements were not as numerous in the early years of maximal employment as in the later years of reduced employment. The record-keeping has been exemplary through what is known as the Ontario Uranium Nominal Roll. It contains over fifteen thousand names; eighty-one deaths have been certified as due to lung cancer, about twice the number expected. Risk estimates for this group are about the same as for U.S. miners. However, the study is really too young to have the same quantitative significance as the U.S. and Czech work. In the future, it will be more mature, but the exposures have declined considerably, and they were never as high as in the other studies (only 21 to 180 WLM in three categories).^(a,b)

D. Other Miners

Miners working in a variety of hard-rock mines are expected to exceed normal incidences of lung cancer because these mines frequently have concentrations of radon daughters well above background. The levels are seldom as high as in uranium mines, but they are significant nevertheless. Formal studies, as related earlier, have been carried out for Swedish iron, zinc, and lead miners; fluorspar miners in Newfoundland; British underground iron miners; U.S. base-metal miners working underground in hard-rock formations; and South African gold miners. Some of these were described in the 1972 UNSCEAR report and expanded upon in the 1977 version (UNSCEAR 1977). The Newfoundland and Swedish populations are also reviewed in some detail in the most recent BEIR report (BEIR III 1980) and the very recent NCRP report (NCRP 1984a).

The total population in Newfoundland's mines is 2,414, with records over the period 1933 to 1971. Estimated radon daughter concentrations were 2 to 8 WL up to 1960, below 0.5 WL since 1960. There was a clear increase in incidence of lung cancer, which correlated well with cumulative exposure. The complications of smoking are analyzed. Risk estimates per unit radon daughter exposure are in the same range as those derived from the uranium miners. (The cogent references can be found in BEIR III.)

The Swedish metal miners, composing a small group, have the advantage of very long follow-up times. BEIR III concludes that the data are insufficient for determination of risk coefficients. However, others have calculated tentative risks in the

(a) A recent addition is miners being traced through the Workman's Compensation Board.

(b) Further details can be found in the paper by Stewart et al. (e.g., Myers and Stewart 1979).

Swedish miner group. Two of the three groups appear to have considerably higher risk than the uranium miners. If true, it may indicate greater importance of factors other than radiation exposure. However, the study is still in progress, and the Swedish investigators need more time.

The British hematite miners showed a significant, but not large, excess of lung cancers. Exposure levels were low (0.15 to 3.2 WL). Even lower exposure levels (0.1 to 0.2 WL) were reported for the U.S. base-metal miners. These populations contribute little to the total picture because of the low exposure levels. The South African gold miners, who show no excess of lung cancer, had comparable exposure levels (0.1 to 0.3 WL on the average).

E. Commentary on the Epidemiologic Results

Even the brief summary given above indicates that research on the epidemiology of radon daughter effects has been active in many parts of the world. Relative to many of the research undertakings concerning radioactivity and health, the U.S. contributions have been significant, but do not preempt the field as they have in some other areas. Yet, the contributions of U.S. work, including the later years of the AEC, are significant and of as high quality as can be mustered in a field with so many difficulties.

The primary reasons for engaging in and supporting these activities are (1) the contribution they make toward establishing dose-response relationships, (2) the development of estimates of risk, and (3) the establishment of standards.

We saw in chapter 1 that the radium data, among the best we have, can support more than one interpretation of dose-response relationships, particularly in the low-dose domain. The data from the uranium miner studies contain less congruent populations and a less certain estimate of dose. The easy way out is to assume linearity as conservative and decide that the data are "not inconsistent" with a linear expression. This may be as far as we will ever get, but continuation of the work until every possible data point has been gathered is important.

Risk estimates from the miner data cover a surprisingly narrow range when the wide separation of sources and populations is taken into account. UNSCEAR (1977) remarks on the higher cancer induction rates derived from mortality experience in uranium and other miners compared to radiation from external sources (i.e., 10 to 25 $\times 10^{-6}$ /rad or kerma of absorbed dose in the Japanese bomb survivors and British spondylitics versus 40 to 180 $\times 10^{-6}$ /rad or kerma for the miner populations).^(a) If true, this may indicate that a cofactor or cofactors in the mine exposures is influencing the incidence rates. However, in view of the problems of establishing the radiation dose in the Japanese populations and the many possibilities for error in the miner studies, these estimates do not seem alarmingly different. Indeed, despite the much-discussed problems of the miner epidemiology, the final figures seem to have reasonable consistency and indicate that the whole effort is worthwhile. A composite graph showing effects in all of the human epidemiologic studies it is feasible to plot, as well as summary data from the animal experiments, is shown as figure 3.2.

(a) BEIR III gives revised figures of 22 to 45/10⁶/yr/rad for the miners versus about 3 cases/10⁶/yr/rem for the Japanese bomb survivors and the British spondylitics.

FIGURE 3.2. Composite of dose-effect relationships on the basis of cumulative exposure. (Courtesy of F. T. Cross, modified from figure 11.1 in NCRP 1984a.)

Also of use to the reader is the very complete summary of published dose calculations and derived occupational exposure limits from the many studies contained in this chapter given in table 4.1 in NCRP Report 78 (NCRP 1984a).

The establishment of standards for the miners is a book in itself. Every major report of epidemiologic work has either been issued with implications for allowable exposures or has had figures derived by others for this purpose. We are greatly indebted to Fredrick Cross and coworkers at Pacific Northwest Laboratory (PNL) for the sophisticated in-depth evaluation of methods for setting occupational health standards for uranium miners already mentioned (Cross et al. 1974). This report considers all aspects, but especially useful for our needs is its table 2.3, a summary of published dose calculations, epidemiologic findings, and recommendations for exposure standards from the original Evans and Goodman paper (1940) to the work of Harley and Pasternack in 1972. This table resulted from a project development report prepared in 1968 by an ad hoc task force from PNL (Cross et al. 1968). It provides not only succinct analyses of the scientific problems, but full details of all research and development programs in progress, including their sponsors and coordination of other Battelle programs with them. Suggestions for research abound. These include the conclusion that much more needs to be done on the uncombined radon daughters and their role in producing biological effects.

An updated version of all of this work is reproduced in the recent NCRP report (NCRP 1984a).

VII. The Spas and Therapeutic Mines

It should be no surprise that radon found favor as a therapeutic nostrum much as did ^{226}Ra (see chapter 1).^(a) There are many areas of the world where high concentrations of radon and its daughters exist in natural water supplies. In addition, many former mines with high radon concentrations in the air have been pressed into service as treatment centers, and special chambers called "emanatoriums" have been constructed at major medical centers. The uses of radon water go back to antiquity, while the use of air with high radon concentrations developed primarily in the early twentieth century.

The purposes were identical to those of the therapeutic injections of radium: "stimulation" of bodily functions to combat various chronic diseases or the nonspecific ailments of advancing years. In contrast to the uses of radium, which occurred to a large extent in the United States, these practices were much more centered in Europe. The famous hot springs (i.e., spas) of central Europe were paramount centers. Many of them were located in areas with the same geological formations as at Schneeberg and Joachimsthal. They had waters with both high temperatures and high contents of dissolved radon.^(b)

The total populations exposed may have been of the same order as those given radium as a nostrum. We have no adequate records, at least none that have been analyzed. Fortunately, the short half-life and short retention time of radon and most of its daughters meant short exposure times for all exposed persons, save the workers in these establishments. There has been no epidemic of radiation-induced lesions to put beside the uranium miner saga or the radium saga. Nevertheless, some interesting work has been done that deserves review. In a sense, it is more observational than experimental, and the U.S. participation has been relatively minor. Yet, it is a part of the history of radioactivity and health.

A. The Spas and Therapeutic Galleries in Europe

Typical of the great European spas is Badgastein, in the Austrian Alps. In an enthusiastic book written by Hans Hannau, a Floridian, we read the following:

For Badgastein sits within a framework of Nature's most magnificent scenery. It is an international resort and health center . . . an interesting town in which to meet celebrities, kings, maharajas, beautiful women, statesmen, actors, poets and composers from all over the world. (Hannau, undated, inside front dust jacket)

There are eighteen or more radon-containing springs at Badgastein, whose water is transmitted by a system of pipes and tanks to the central watering areas and even to the individual hotel rooms. The water is either drunk or bathed in, according to the prescription of the attending physician.

In addition, Badgastein and other centers now have what are known as thermal galleries. For example, a worked-out gold mine was found to have high concentrations of radon and also, perhaps because of the proximity to the hot

(a) This is separate from the use of encapsulated radon sources in therapeutic radiology, where it is the gamma radiation that is important.

(b) The "metered radon solutions" of Russia and Eastern Europe (see footnote b, page 165) were prepared in laboratories and distributed to the points of therapy. Details concerning these have been described by Andreev (1984) in reference material kindly supplied by Dr. Carl Reich (see next section).

water sources, quite high ambient temperatures. Again we will let Hannau give the details:

...an unexpected increase in temperature was remarked within the recesses of the mine. Chemical research disclosed that this was due to secondary uranium deposits contained in the rocks and compassing a thin layer over the walls of the tunnel. [This was, of course, *not* the source of the high temperatures.] The deposits were rich in radon. Workers at the mine who suffered from rheumatism soon found themselves feeling better. And here for the first time was apparent evidence that radon emanations were effective as a curative treatment for certain ailments.

These Stollen, or tunnels, are almost a mile and a half long. The temperature within rises to almost 90°F. Visitors proceed through the *Stollenkurhaus*—the Air Spa Building—immediately adjacent to the Galleries, whence they proceed on trains through the tunnels, with special nurses in attendance. The natural hot-air emanations are used in the treatment of illnesses that are favorably affected by a combination of warmth and inhalation of radon. Chronic inflammatory forms of rheumatism, inflammations of muscles and nerves, disturbances of the vertebral column, gout, certain circulation disorders, sequels to poliomyelitis, certain allergies, and hormonal and vegetative troubles are treated here. The results are considered as favorable as those of the thermal baths and, in many cases, more so. (Hannau, undated, p. 49)

Figure 3.3 gives an idea of the extent of development around one of these thermal galleries, while figure 3.4 illustrates the opulence of a resort like Badgastein.

A summary of the medical benefits alleged to be associated with treatments at these resorts is the following:

The effects of the waters, according to some medical writers, are based on at least three factors: the general stimulation that every watering cure produces; the special properties peculiar to natural hot water; and, finally, the effects of the inert gas radon contained in the thermal waters. The last is not to be confused with the effects of radioactive matter in concentrated form which is stored in the body. This gaseous radon is exhaled or eliminated from the body after a very short time (normally two to four hours), whether absorbed by inhalation, drinking, or bathing. In the process, however, the radon stimulates the functions of all the body cells, relieves pain, in neuritis and rheumatic complaints, and provides a special stimulus to the endocrine glands. . . . The source of the foregoing statements is the writings of various medical authors. (Hannau, undated, pp. 16, 47)

This language is typical of that used since antiquity to describe these "cures." As scientists, we tend to dismiss them as mostly psychosomatic or figments of the imagination. Yet, the field of toxicology is rife with instances where low doses of otherwise harmful substances appear to "stimulate." In the radiation field, we have now a formal collection of such instances, with the research behind them in a book by Luckey (1980), and more recently, a symposium, the proceedings of which are yet to be published. Only the future can tell.

Figure 3.5 illustrates one possible reason that at least the male customers feel "stimulated" and in improved health after such a treatment. Parenthetically, one must wonder at the radiation exposure of such attendants if they should work for long periods in these thermal galleries.

B. Spas and Therapeutic Mines in the United States

While the United States has a good supply of hot springs, few if any have been used for radon treatments in the manner of the European spas. What interest

FIGURE 3.3. Main building and entrance to thermal rock galleries at Boeckstein. (Hannau undated. Reprinted with permission of the author.)

FIGURE 3.4. General view of Badgastein. (Hannau undated. Reprinted with permission of the author.)

FIGURE 3.5. Treatments in the thermal gallery, Badgastein. (Hannau undated. Reprinted with permission of the author.)

there is has been of relatively recent origin. A worked-out uranium mine in Montana has received the most attention. In a small book entitled *Arthritis and Radioactivity*, Wade V. Lewis tells the story of Montana's Free Enterprise Uranium-Radon Mine. It is hardly as opulent as Badgastein, but testimonials are as numerous and enthusiastic. This mine is not at high temperature, and the principal exposure is thus to radon and its daughters (Lewis 1955).

When a topical symposium of the Health Physics Society was held at the venerable spa at Saratoga Springs, New York, the levels of radon and of radium in the waters were considered informally. However, nothing about this appeared in the published proceedings. There was a paper given by people from the Environmental Protection Agency on ^{222}Rn in potable water (Gesell, Pritchard, and Hess 1982). They reported on radon content of water for seven areas of the United States, and in Finland, Great Britain, Japan, New Zealand, and Israel. No special effort was made to concentrate on spas.

C. The Radon Levels Involved

A considerable effort was expended by Austrian, Danish, German, and Czech investigators to determine the concentrations of radon in the thermal galleries. These considered primarily the amounts in the water and in air, but secondarily amounts in blood, excreta, etc., and "metabolism" of the several nuclides.

Amounts in air clustered around 10^{-9} Ci/l, i.e., in the same range as the air in the mines.^(a) Recalculated in working levels, the amounts in air range from less than one to as high as about 100 WL. The amounts in water around the spas tended to be higher in general, with average maxima from 1,000 pCi/l to 10,000 pCi/l. Measurements around Badgastein can be found in Pohl-Rüling and Scheminzky (1954), Aurand, Jacobi, and Schraub (1956), Aurand et al. (1960), and Pohl (1962). Concentrations in natural waters around other European spas are given by Hursh et al. (1965).^(b) This last report includes an average maximum of 2,000 pCi Ra/l in water at a spa named Kronthal (Taunus). Some of this research considers also radon concentration in free air in the neighborhood of the spas. Pohl-Rüling and Fischer (1982) quote a mean concentration in the water at Badgastein of ^{222}Rn at 4,000 pCi/l, while the atmosphere in the thermal gallery had a mean concentration of 3,000 pCi/l. Also, Gesell, Pritchard, and Hess (1982) present the range for a large variety of samples, e.g., 0 to 30,000 pCi/l with 25% of the locations exceeding 2,000 pCi/l and 5% exceeding 10,000 pCi/l. Andrews and Wood (1974) report ^{226}Ra , ^{222}Rn , and ^{210}Pb levels in the waters of Bath, England, and show levels of ^{222}Rn well over 2,000 pCi/l.

Measurements are not readily available for the therapeutic mines in the United States. The more legitimate ones^(c) are near ore bodies of the same or lower uranium content as the European therapeutic galleries. Levels of 1,000 pCi/l or below would therefore be expected.

Of special interest is early work from Copenhagen by Jansen and Schultzer (1926). Jansen was "Director of the Emanatorium" at the Radium Station of the Finsen Institute of Copenhagen and was searching for the "optimal therapeutic

(a) Some of the earlier reports were in "impulses/min," and these have been converted very approximately.

(b) We will consider springs not associated with spas in section X.

(c) There are some that consist only of caves lined with uranium placed there by the owners. These contain little radon.

level" of radon to use in his emanatorium. They state that their original doses were very small, e.g., 1,000 M.U. (Mache units) daily by mouth, or 2 to 4 M.U./l of air in the emanatoria. These convert to about 700 to 1,400 pCi/l or 7 to 14 WL in the air assuming equilibrium with radon daughters; no reason for any great worry for short exposures. However, they quote also increasing the dose to as much as 300,000 M.U. (about 10^{-4} Ci/l) in the water and 5 to 600 M.U./l (1,800 to 218,000 pCi/l or 18 to 2,180 WL) in the air, assuming equilibrium. Even at these levels they reported not much obvious effect either therapeutic or deleterious. Indeed, the authors worried more about the gamma dose from the degradation products deposited on the walls and floor of the emanatorium than the internal dose from radon and its daughters.

D. The Possibility of Effects

We have already remarked upon the multiplicity of testimonials and the enthusiasm of patients and physicians for the alleged therapeutic effects of these exposures. Organized scientific medicine still regards these as in the realm of folklore, and we can go no further at present, except to say that perhaps nature has not yet revealed all of her secrets to us.

Fortunately, as mentioned earlier, the short physical half-life of radon and its early daughters plus rapid elimination from the body (biological half-life less than one hour, Suomela and Kahlos 1972; Hursh et al. 1965)^(a) have spared us a repetition of the deleterious effects seen in the iatrogenic cases of poisoning by ^{226}Ra , ^{228}Ra , and ^{224}Ra . Admittedly the single doses have sometimes been high, but they are short-lived. Long-term epidemiologic study of the thousands of patients who have "taken the cure" over the years would probably be fruitless. On the other hand, long-term effects on hematopoietic tissue or production of lung cancer might conceivably occur in the employees who conducted patients into the galleries and ministered to their needs during the therapy sessions. The numbers of such employees may be too small to support bona fide epidemiology. Nevertheless, follow-up of these individuals should not be dismissed out-of-hand. For example, Pohl-Rüling and Fischer (1982) have studied chromosome aberrations in inhabitants and workers at Badgastein. There were definite increases in aberrations in persons continually irradiated by the environment, and a dose-response curve could be drawn. However, no link could be established between the presence of these changes (mostly dicentrics) and deleterious effects, i.e., pathology.

At the 1973 Congress of the International Radiation Protection Association, several Japanese investigators (Maeda et al. 1974) attempted to distinguish between the cause of death in a population living near a "radiation-rich hot spring" and a regional cohort. No noticeable difference was found.^(b)

(a) Hursh et al. measured loss by direct measurement in volunteer subjects who drank radon water using breath, blood, and urine for radon and a whole-body counter for RaC, while Suomela and Kahlos used the ^{214}Bi elimination only.

(b) Very recently, Carl J. Reich, M.D., provided this author with a draft note intended for the journal, *Health Physics*. He states that over 100,000 individuals have visited the radon mines near Boulder, Montana, and he refers to a clinical study of a portion of this population. He also states that up to one million patients are treated annually in the spas of "radon laboratories" of Russia. Perhaps there is, after all, a population large enough for epidemiologic study. Dr. Reich also gives a few estimates of dose in units of working level (Reich 1986).

As will be seen from the titles of the several papers quoted in this section, a reasonable amount of pharmacodynamics was done over the years around these exposure modalities, some of it of considerable value to the uranium miner problem since relatively little experimental work has been done with the miners.

This is an area of more interest than substance from the standpoint of research. However, as a facet in the history of radioactivity and health it presents items of interest and some unanswered questions. It has recently been expanded greatly in the area of possible indoor exposures in a variety of situations. A later section will consider these very recent additions.

VIII. Experimental Animal Research

A. Early Studies

We have already alluded to some of the earlier experimental work on radon with animals. It almost always utilized quite high concentrations, and there was little understanding, of course, of the role of the daughter products. This makes attempts to reconstruct the doses very difficult. About all these early experiments did was to show that radon was a toxic gas.

The animal experiments up to date of writing have been summarized well by Morken (1955c), by Cross et al. (1968, 1974, 1986), and in NCRP (1984a). The chronology begins in 1904 with some Russian work by London (1904); a dissertation by Gol'dberg (1904); and some French work by Bouchard, Curie, and Balthazard (1904), and Bouchard and Balthazard (1906). These were all very acute exposures.

Work in the Emanatorium (Copenhagen) by Jansen and Schultzer in 1926 showed that suckling rats were more sensitive than adults. It was followed by a rather ingenious second experiment (Schultzer 1926) to separate effects of the radiation within the animals from the "hard" radiation outside the animal arising from the decomposition products deposited in the Emanatorium. They placed a radium source in a paraffin capsule inside the animal. The radon could diffuse through and enter the blood stream, thus irradiating the animal internally; but the radium did not dissolve. They kept the cage well ventilated with room or outside air so that no radon or daughters would enter by inhalation. Strengths of the radium-bromide solution in the capsule were adjusted to provide internal radon concentrations similar to those after inhalation in their first experiment. These "capsule" animals were observed for nine weeks, and no biological effects were seen compared to the controls. Therefore, the authors reasoned, the effects in the first experiment must have been from the hard radiation (i.e., gamma rays) which bombarded the animals from without. Alas! So near and yet so far! They recognized the role of the daughters formed outside of the animals, but muffed the concept of their importance on inhalation.

The acute and semiacute experiments that utilized the inhalation route demonstrated marked effects in the lungs and other tissues such as hyperemia, generalized inflammation, etc., but no lung cancers. In the tradition of all animal toxicology, until the postwar work showed the way, the investigators were too impatient and nearly always terminated the experiments during the latent period for the development of cancer. This early research, including German, Austrian, and Czech work cited in the reviews, also established many facts about the metabolism of radon. However, even as late as World War II

(e.g., Lorenz 1944; Hollcroft and Lorenz 1951) the animal work did not really imitate the miner exposure situation. Also, only the work of Read and Mottram (1939) and of Jackson (1940) addressed the maximum permissible (tolerance) exposure levels directly.

B. The Post-World-War-II Years

Even though the AEC was slow to support epidemiologic work with the miners or control work in the mines, it quickly encouraged and supported animal studies with radon. Centers for such work were the Rochester Project and later Pacific Northwest Laboratory and Colorado State University. At the same time, the Commissariat à l'Energie Atomique (CEA) in France mounted a rather extensive experimental program with animals. Some work was done at other laboratories such as the Naval Radiological Defense Laboratory (Cohn, Skow, and Gong 1953), but these studies did not continue for extended periods. Projects at Rochester, CEA, and PNL have continued over two to three decades.

A full review of much of this work can be found in the proceedings of the many meetings and organizations we have already discussed. We will review what was done primarily for highlights and from the standpoint of concepts and philosophy and leave the details for these reviews.

1. Work at the University of Rochester Atomic Energy Project

Animal research on radon at Rochester began with the checks by Shapiro and Bale on Bale's ideas regarding the role of the inhaled daughters. This was described in the dosimetry section.

Work aimed at measuring effects began with the Ph.D. thesis of Donald Morken in the mid-1950s. The first experiment used mice and an exposure rig (Morken 1955b) that essentially removed all of the preformed daughter products from the circulating air. He determined the LD_{50} for thirty days. When calculated in terms of absorbed energy in ergs per gram, the LD_{50} was very similar to that of 250-kV x rays.^(a) In view of the vaunted extra biological effectiveness of alpha particles, this result was a surprise, but there was no doubt about it (Morken 1955a,c). Also, the tissue pathology looked very similar to effects from acute x-irradiation (Scott 1955). It could only be concluded that, for the processes causing acute deaths in these mice, there was little dependence on the type of radiation employed.

There were some differences in the pathology between radon and x rays when a less acute dose was given. This work permitted observations up to seven months (Scott 1955). Proliferation of bronchial epithelial cells was obvious, and there were kidney changes reminiscent of those seen after intravenous injection of ^{210}Po (see chapter 4).

(a) Morken expressed his doses as an activity-time product, mCi-hr/l. This was before the working level had come into general use. Also, since the exposures were to almost pure radon, the working level notation could not apply anyway. Locally this unit of Morken's was referred to as "The Mork" somewhat in analogy to the old Mache unit. However, this usage never got into print or beyond "in-house" discussions. It is unfortunate in many ways that some such unit for radon exposure has not found general use. We are now in the situation where radon gas is recorded as a concentration only (e.g., picocuries per liter) while the unit for the daughters includes a time factor, i.e., working level month. The alternative is to put the daughter unit back to a concentration only.

Later reports used large enough groups of animals to measure life-span shortening, body weight, and the hemogram (Morken 1961, 1964; Morken and Scott 1966). Life shortening was proportional to total accumulated dose. On a multiple-exposure regime, it appeared that the lethal injury was half repaired in two weeks.

Of particular interest in these experiments, and still unexplained, is the fact that the red cell count remained depressed for a considerable period or even permanently. It did not recover nearly as rapidly as after treatment with external radiation sources. On a multiple-dose regime, the red cell count was depressed by a fixed amount following the first dose and remained at this level for about one year. It then merged with that of the controls. It was not further influenced by additional doses. Following a single larger dose, it just remained depressed for a year or more.

Radon produced less life shortening in the mouse, per unit of radiologic dose, than did injected ^{210}Po .

In none of these experiments were any true lung cancers found, even though there were some indications of metaplasia. It began to look as though even modern animal experiments were going to have difficulty reproducing the lesions seen in the miners.

At about this time, the Rochester group turned to a larger, more elaborate exposure system, which could accommodate many small animals and a few dogs simultaneously. It contained steady-state concentrations of the daughters at fractions of the equilibrium value on the order of 0.9, 0.45, and 0.25 for RaA, RaB, and RaC, respectively, and about 20% unattached RaA activity (Mercer and Stowe 1970). In toto, these experiments involved about two thousand mice, one hundred rats, and eighty dogs, plus suitable controls. Details of the results can be seen in the Morken references given below and in NCRP Report No. 78 (1984a).

The work with mice was chronic, with cumulative exposures up to 72,000 WLM and average total doses to lung up to 11,000 rad. There were several experiments with different exposure periods (Morken 1973a,b). There were some serial sacrifices and emphasis on gross and microscopic pathology rather than life-span shortening.

Again, precancerous changes were seen regularly. There were tumors much like those that arise spontaneously, but they showed a greater tendency toward malignancy. On the whole, however, the pathological changes were still not very similar to the bronchogenic carcinomas seen in man.

The exposure of the dogs was also chronic. Calculated working level months in dosimetry and pilot experiments were 1,950 or 3,900 and a tracheal dose of about 10,000 to 20,000 rad. There was also a large exposure-response study with fifty-one dogs and exposures from 200 to 10,000 WLM. The pathological changes were classed as "subtle" and largely inflammatory, and they were not clearly related to dose. No frank cancers were found. Even a special experiment giving tracheo-bronchial doses up to 50,000 rad did not change the picture (Morken 1973b).

The work with rats involved average doses to lung of 4,300 rad and much higher doses to the trachea. Again the pathological changes were not impressive, although some metaplasia appeared in lungs.

The Rochester experiments during the period of pertinence to this book were thus notable for the lack of production of radiation-specific tumors. The only permanent changes in the lung were in the alveoli, and they were not of the type expected to lead to cancer.

2. Work at Pacific Northwest Laboratory

The experimental work with animals at PNL began later than that at Rochester. It differed in having the Syrian Golden hamster replace the mouse, and in emphasizing exposures to aerosols of radon and daughters mixed with other possible causative agents in the mines, such as uranium ore dust and diesel exhaust fumes. Also, dogs were trained to smoke cigarettes,^(a) and thus an overt study could be made of the possible effects of tobacco smoke with and without exposure to the surrogate mine aerosols.

The exposure chamber array was quite elaborate. For the hamsters, it consisted of a special plexiglass chamber into which cages could be placed. For the dogs, the exposure was of the mouth and nose and nose-only type. The cigarette smoking was arranged through a special mask that was not used simultaneously with the experimental aerosol exposures. The chamber arrangements are shown in figure 3.6.

The work with the Syrian Golden hamster involved over six hundred animals in six groups with various combinations of radon and daughters, with or without uranium ore dust, uranium ore dust alone, diesel engine exhaust alone, and one group with everything plus the usual controls. The uranium ore dust was carnotite.

Several neoplastic lesions were seen in the group receiving radon and daughters and in the group receiving also uranium ore dust. Lung tumors appeared in these same groups at exposures above 8,000 WLM. There was severe squamous metaplasia in the group that received everything. The tumors were, on the whole, not particularly invasive, with one exception.

Other respiratory-tract lesions were quite general. The uranium ore dust and diesel fumes alone provoked inflammatory and proliferative processes, but no precancerous lesions.

The incidence of true cancer was still relatively low. Only four hamsters from over five hundred experimental animals developed squamous carcinoma. This was a greater incidence than in the Rochester experiments, but it was hardly a large increase. It led the investigators to conclude that the Syrian Golden hamster is refractory to carcinoma induction, especially to agents of low carcinogenic potential, and that it is not a good animal model for respiratory cancer in man.^(b)

The experiments with beagles involved sixty-nine animals, including nine controls that received room air. The others were equally divided into groups receiving radon and daughters and uranium ore dust, the same plus cigarette smoke, and cigarette smoke alone. (Support for this work came primarily from AEC until the later phases, which were supported also by the NIEHS.) There was no work with diesel exhaust fumes in the dog experiment.^(c)

There were eight lung neoplasms in the nineteen dogs remaining (dogs had been removed earlier for detection of early effects) that had received radon plus daughters and uranium ore, two in the group receiving the same but also smoking cigarettes. The dogs that smoked but did not receive radon, or radon

(a) The beagles became quite fond of their daily smokes, or so it seemed.

(b) The reasons for choosing this species in the first place will be taken up in chapter 9.

(c) An extensive study of the toxicology of diesel exhaust aerosols is under way at the Inhalation Toxicology Research Institute, Lovelace Foundation (ITRI 1979) as part of the "new look" for former AEC-ERDA Laboratories.

FIGURE 3.6. Exposure chamber designed for head-only exposures of ten dogs to radon daughters with uranium ore dust as used at Pacific Northwest Laboratory. (Reprinted from Cross et al. 1978, p. 56.)

in combination with other substances, showed many pulmonary changes, but not lung cancer. As in the hamsters, the animals developing tumors had quite high cumulative radiation exposures. In general, the development of lung cancer in both of these experiments at PNL occurred only at doses nearly two

orders of magnitude higher than those associated with lung cancer in the miners.^(a) The authors speculate that one reason may lie in the shorter life span of the animals compared to man. The longer human life span may allow more time for carcinogenesis to be expressed. Also, the dose nominally calculated in the animal work may be overstated because of "wasted radiation" (i.e., a lower dose may have initiated the process, but the life span was over before it could be expressed).

The fact that cigarette smoke seemed to mitigate rather than increase the effects of radon was again something of a surprise. The authors suggest increased thickness of the mucus layer and a net stimulation of mucociliary clearance as possible reasons. We have already encountered this idea in the human studies. When respiratory-tract tumors developed in animals, they originated in the bronchi, alveoli, or nasal septa. The tumors in the uranium miners are bronchogenic and primarily in the smaller bronchi. This difference may represent a species difference or dosimetric difference because of the smaller dimensions of the animal's pulmonary tree, an issue that cannot be decided at the present juncture.

There were many follow-up studies, including exposures of dogs to carnotite uranium ore dust alone, i.e., without radon or daughters, and a fairly extensive program using rats exposed to mixtures of radon plus daughters and carnotite ore dust. These were intended to develop dose-response curves, and the exposures were not life-span.

The results^(b) in the dogs suggested differences in the pulmonary lesions when exposure was to ore dust alone and slower development and reduced degree of pulmonary fibrosis when radon plus daughters were absent. The rats showed no change in mortality patterns at exposures up to 2,500 WLM, but there was significant life-span shortening at 5,000 WLM (about 1,000 rad mean lung dose) or more. Interesting phenomena appeared in the occurrence of lung carcinomas in the rats. There was an increase in apparent lung cancer risk with decrease in radon daughter exposure rate (life-span effect?), with an increase in the portion of *unattached* radon daughters, and an increase in radon daughter disequilibrium. It also appeared that the ore dust contributed to the prevalence of nonneoplastic lesions, but not to the development of tumors, at least at the higher radon daughter exposure levels studied. Thus, this new research confirmed what was clear from the earlier work, i.e., that it is possible to produce frank lung tumors in animals with radon plus daughters alone. It also indicated that there are still unresolved questions. In addition to those involving unattached atoms, disequilibrium, and exposure rate, the chances of some species differences persist. These will be seen again in the French work about to be discussed.

3. Animal Studies at the Commissariat à l'Énergie Atomique, Razès (Limoges), France

The French not only have a strong nuclear energy program but have engaged in much supporting research. Lafuma's laboratory has been active in

(a) Lung cancers were subsequently observed quite late after exposure in a few animals (not in the life-span experiment) exposed to much lower levels of radon daughters (Cross, private communication 1984).

(b) The author is indebted to F. T. Cross for a specially prepared summary of these relatively recent and ongoing experiments at PNL.

internal-emitter research for many years. The radon work is moderately recent and was another overt attempt to correlate animal carcinogenesis with events in the uranium mines. The test animal was the rat (Sprague-Dawley).

The French investigators used moderately large chambers for their early work. These could hold up to one hundred animals and contained an atmosphere in which decay products were reduced to about 0.01 of equilibrium. Later they used a very large chamber holding about three hundred rats and an atmosphere of radon either in full equilibrium with daughters, 20% to 30%, or as low as 1% of equilibrium. In some experiments, either stable cerium hydroxide or uranium ore dust was added as well. Exposures were of the chronic type. (Chameaud et al. 1974, 1976, 1978).

The lungs of about four hundred of eight hundred rats were examined both grossly and microscopically. A total of 250 benign and malignant tumors were found! In addition, two types of metaplasia were present, one in the alveoli, the other in the bronchioles. Adenocarcinomas appeared that were invasive, although limited to the lung. Furthermore, there were tumors at relatively low exposures (500 WLM) relative to the PNL life-span studies and Rochester findings, although the maximum incidence appeared at 9,600 WLM (96 days at 5 hr/day with 20% to 30% daughter products). There were fewer tumors at 14,000 WLM and none at 21,000 WLM or in the controls. There were more carcinomas or adenocarcinomas in the range of 4,500 to 9,600 WLM, more adenomas in the lower brackets, and a maximal number of epidermoid carcinomas at 9,600 WLM. There was also an optimal exposure rate and a progression in both lesion type and latent period with dose and dose rate.

The addition of stable cerium advanced by up to three months the appearance of cancers induced by radon daughters. By contrast, uranium ore dust seemed to have little influence.

The effect of adding tobacco smoke was found to depend on the temporal sequence of exposures to it and to radon daughters. When exposure to tobacco smoke followed all of the exposures to radon daughters, the total tumor yield was greater than that produced by radon daughters alone. When smoking occurred first, there was no change in the tumor yield produced by radon daughters alone (Chameaud et al. 1981). These findings contrast to those found in dogs at PNL (see section 2 above), where the tobacco smoke and radon daughter exposures were alternated and given in the same day. Yet, on the whole, the researchers at CEA and PNL find more similarities than differences between each other and between animals and man.

There is no question that the French and PNL experiments make the rat look more like man than any other test animal. Yet, earlier work with the rat (e.g., at Rochester), which involved both standard rats and specific pathogen-free animals of the same strain, showed much lower incidence of lung tumors.

4. Commentary on the Animal Research

More experimental work needs to be done that can explain the differences in results among the various laboratories or between animals and man.^(a) These

(a) A cogent summary of the dilemmas in the radon work and evidence of strong carcinogenic action of other inhaled radionuclides are found in the paper by Bair (1970) at the Gatlinburg symposium in 1969 and in ICRP Publication 31 (1980).

differences appear to reside primarily in tumorigenesis. Metabolic effects and most other pathology seem to be much more uniform among laboratories and species for a given set of exposure conditions. We know that inbred strains of animals from the same original stock can show marked individual differences after a few generations in a new location. We know also that many subtle differences appear at the cellular level, e.g., in tissue cultures, in different laboratories. All we can conclude is that our knowledge is far from complete. The idea of unknown endogenous or exogenous cofactors for carcinogenesis remains an attractive avenue of thought.^(a)

Despite the differences among laboratories and apparently between man and the animal models, there is no question that the animal work has been very useful, particularly for establishing effects over a very wide range of doses and, of course, for pathologic and physiologic responses and for dosimetry data as described in section V. Observations in animals not unequivocally demonstrated in man include an increase in tumor production with increase in the unattached fraction of radon daughters and in disequilibrium and the importance of temporal sequence of exposure in developing effects of cigarette smoke and radon daughters. However, these may not be real differences. Only further investigation can decide these points.

IX. Research on Control of the Mine Environment

Most of the efforts to control exposures in the mines have been engineering projects. Yet, the biomedical community got involved, partly because many of the personnel from PHS and a few of the AEC personnel concerned were industrial engineers or industrial hygienists. They got involved in advising on ventilation and measuring its effectiveness. They also got involved in measures to seal the rock formations to prevent egress of radon.

Perhaps the areas of most pertinence to this review of internal emitter toxicology are instrument design, aerosol research, and respirators.

A. Instrument Design

Many of those connected with research on radioactivity were either physicists or were otherwise versed in electronics and had already developed instrumentation for their own programs. They saw the needs and sometimes teamed up with instrument manufacturers to design and provide equipment for the rapid measurement of radon daughters and thus of the working level. Other individuals and groups got involved in exploration of the utility of whole-body counters to measure residual radioactivity from radon progeny. The AEC supported development of surveillance monitoring equipment at the Health and Safety Laboratory (HASL) in New York, at MIT (simultaneous detection of radon gas and radon daughters), Idaho Operations Office, Colorado State University, the Eberline Instrument Corporation, the General Electric Company, and others. The Public Health Service brought in its regional laboratories.

(a) When we review the genesis of lung cancer by plutonium in chapter 9 we will see what appears to be the inverse of the interspecies relationship with radon.

Devices for air characterization were built along two distinct lines, those intended for sampling of a general area with considerable sensitivity and devices to be worn on the person to give useful, but not highly accurate, readings. The "Instant Working Level Meter" from MIT (Groer, Evans, and Gordon 1973) is a good example of the former; it could evaluate the working levels present in about four minutes.

B. Aerosol Research^(a)

Aerosol research was most active at Rochester (basic work), Los Alamos (filters, absorbers, particle-size characterization), HASL (mixture of basic and applied), PNL (air cleaning methods), Colorado State (characterization), the Bureau of Mines (applied studies), and at some of the centers abroad.

C. Respirators

Development of respirators, which at long last the miners were persuaded to wear, was concentrated by tradition in the Bureau of Mines and the manufacturers of industrial hygiene equipment. However, the Colorado State University group had a contract for evaluation of respiratory protective equipment, PNL worked on a respirator using electrostatic precipitation, and several laboratories with good respiratory physiologists were invited to participate in the AEC-sponsored conferences on respirators. As always, the chief problem with respirators was the weight of those with a full face mask and supplied air, and the fit without leaks of the lighter, simpler devices, which filter out the dust and thereby the attached daughters.

D. Bioassay

A final area associated with control is bioassay. We have already referred to measurement of ^{210}Po or ^{214}Bi in urine. This was extended by Stuart Black of the PHS from the miners to measuring radium daughters excreted by mules that had worked in the mines. The mule, being larger than man, would put out more activity and thus be further above the sensitivity threshold of the methods.

Probably the most useful measurement has been the in-vivo counting of bodily deposits with a variety of whole-body and partial-body counters.

In general, bioassay has not played a central role in evaluating the exposures of miners to radon or its progeny.

X. Environmental and Population Exposures to Radon and Radon Daughters

We have had little to say so far about environmental and population exposures from radioisotopes. Most of our discussion of these will come when we review the entire field in chapters 11 through 15. However, recent keen interest in possible health effects from radon and daughters in the environment^(b) has both stimulated new work and motivated reviews and interpretation of much work already done. It is so closely related to other sections of this review of the radon and uranium miner saga that it should be considered now, rather than waiting for the fuller discussion of environmental work.

(a) Considered in more detail in chapter 9.

(b) This interest is much broader than that around the spas discussed earlier.

Pre-World-War-II studies were made by the Rajewsky group from Frankfurt and by others of the radon concentrations in air and water of central Europe. Interest in such figures was part of a general effort to determine levels of natural background radiation and their possible significance. Newer work has developed around the possibilities of significant radon and daughter exposures in dwellings and workplaces. This work is very fully summarized in the UNSCEAR (1977) report and in two reports from the National Council on Radiation Protection and Measurements (NCRP 1975, 1984b). It is a very active field at present with a section in a special report due very soon from the National Research Council, a summary in the U.K. Radiation Protection Bulletin (Cliff 1978), communiques from the Environmental Protection Agency, etc. This enterprise has required the attention of many researchers in a few centers active in radiation toxicology. While the early work was primarily European, much of the later work has been American.

A. Exposures Indoors

The pioneer in indicating that people who live in stone or brick houses are in an environment of higher radioactivity than those who live in wooden houses was a Swedish student named Hultqvist (1956). He wrote a thesis on measurements of both airborne radioactivity and the relative gamma-ray fluxes in houses and other buildings as a function of the type of building materials used. This was followed by work primarily out of Argonne National Laboratory, the AEC's Health and Safety Laboratory in New York, and New York University. Levels of both radon and thoron and their progeny were determined under a great variety of conditions, as summarized in UNSCEAR (1977) and NCRP (1975).

The big "flap" came about 1966 when it was realized that tailings from uranium mills had been used as fill dirt or for other purposes in the construction of new homes in Grand Junction and Durango, Colorado. The Public Health Service, assisted by AEC personnel, surveyed several thousand homes and decided that about 20% needed remedial action. The prime source was soil under or around the house. The radon levels presented no immediate threat to health. However, in view of the fact that residents occupied the houses approximately 80% of the time (the other 20% they were outdoors), and because of the presence of small children, and the strong reaction of the populace, drastic action was taken. Many houses essentially had their foundation soils removed and replaced at government expense. Even some streets were redone.

The Surgeon General issued guidelines in the 1972 *Code of Federal Regulations*, which recommended remedial action above 0.05 WL, and possible suggested action between 0.01 and 0.05 WL. Many researchers were pressed into service to help make the measurements and interpret them.

A somewhat similar situation was found to prevail in parts of Florida, where phosphate mining was active. The rock formations that were high in phosphate happened also to be rather rich in uranium, and thus the other members of the decay chain. Again, houses were built on land prepared in part from the tailings of the phosphate extraction processes. In both Florida and in Tennessee, where similar phosphate rock mining took place, levels of radon on the order of 1,000 pCi/m³ were found.^(a) This problem led to a request to the NCRP from the

(a) Note that these environmental levels for air are given as *per cubic meter* rather than *per liter*.

governor of Florida and elicited not only a specific response, but a more wide-ranging report, which considered the entire uranium series (NCRP 1984b).

With the energy crunch, still another facet of radon exposure indoors has become active. As houses are being built tighter, and older ones made tight, the air turnover within has been reduced. Measurements indicate that there can be significant increases in radon and radon daughter levels. Is it significant or potentially significant biologically? Cliff (1978) reasons that 90% of lung cancers are due to smoking and that it is unlikely that more than 10% of the remaining cases could be due to radon daughter exposure, i.e., 1% of the total at the levels now extant in U.K. housing. However, he points out that Sweden already has legislation to limit air leakage in homes to less than 0.5 room air changes per hour in winter. The U.K. might go even further. If they should go to 0.2 room air changes per hour, the annual mean population exposure could rise markedly, e.g., 0.78 WLM. This would bring population exposures well above the customary factor of ten to thirty below occupational exposure.

A further consideration is the fact that the indoor exposure conditions favor greater effectiveness of the aerosols. The fraction of unattached ^{218}Po (RaA) is greater, the exposure is greater, the exposure is essentially continuous, and the particle size distribution favors the smaller sizes with greater retention in the respiratory tract.

The NCRP report shows indoor radon concentrations from about 50 pCi/m³ and 70 pCi/m³ in office buildings and wood frame homes in Massachusetts to 1,300 and 1,400 pCi/m³ in Florida and Tennessee phosphate rock mining areas. These are mean figures with a log-normal distribution. Figure 3.7 shows a probit plot from work of George and Breslin (1980) for radon concentrations in picocuries per liter outdoors, on the first floor, and in the cellar of typical buildings in New York. Figure 3.8 illustrates the daughter concentrations in the same manner expressed as annual mean working levels.

These are normal buildings standing in granitic rock or detritus therefrom with normal uranium concentrations. While the means are not high enough to cause immediate concern, they point toward a possibly significant role in inducing lung cancer in some of the extreme cases. This becomes more impressive when one examines the dose equivalent rates to lung or portions thereof, from a number of naturally occurring radionuclides (NCRP 1975, table 29). The dose from 150 pCi/m³ of ^{218}Po (or ^{214}Po) to the segmental bronchioles is by far the highest of all natural radioisotopes at levels of intake consistent with measured exposures.

The more recent NCRP report (1984b) updates the findings, particularly as they apply to the indoor environment. It concludes that under the "right" circumstances, indoor radon and daughters can constitute a major portion of the radiation dose to man from natural sources. The report suggests methods for remedial action and that these be instituted when total exposure to radon daughters for an individual in the population exceeds an annual average of 2 WLM including background. This equates to about 0.04 WL on the average. This is half of the level applied for occupational exposure and represents the first time it has been necessary to set a population level at more than one-tenth of the occupational level. Avoiding this by recommending remedial action at a lower level was considered to involve unacceptable expense and hardship. Also, the total number of cases near or above the limit is probably small.

There is no doubt that some of the hysteria of the general public concerning radiation is showing through in the urgency attached to this work. Yet, if we

FIGURE 3.7. Distribution of annual mean radon concentrations in a few New York buildings. (Redrawn from George and Breslin 1980.)

add some extra radon released from water used for showering, particularly in areas of high natural radon water, a tight house built of granite with more than average uranium content, with perhaps 0.5 room air changes per hour, we are moving clearly toward levels of potential biological significance. This work will undoubtedly continue unless world events occur that make worrying over such relatively minor matters unimportant. The literature is growing rapidly already.

FIGURE 3.8. Distributions of annual mean working levels in the same New York buildings. (Redrawn from George and Breslin 1980.)

Table 3.6 places the figures we have been reviewing in perspective by using representative average exposures (Wrenn 1981).

Currently, the mean population exposures indoors are a comfortable margin below those in the uranium mines. But remember that the uranium miners' got lung cancer down to about 60 CWLM. Thus, the margin of safety is not as comfortably large as we used to think it was.

TABLE 3.6. Representative Exposures to Radon-222 Progeny

Indoors	<0.01	10

^a To nearest order of magnitude.

^b Lifetime or duration of exposure.

^c Includes exposure before mid-1960s.

Source: Reset from Wrenn 1981.

The companion NCRP report already discussed (NCRP 1984a), addresses a wider range of biological problems with radon and its daughter products. These include dosimetry in an environmental atmosphere, in uranium mines, the experimental work with animals, and the all-important epidemiologic studies of the miners. The latter do not extend to the low-level exposures in buildings, of course, since that problem is too new.

B. Exposures Outdoors

The figures in table 3.6 for representative exposures to ²²²Rn progeny indicate a factor of ten difference in working level between indoors and outdoors. Although there are many and sometimes quite large variations in these values, in general the mean concentration of radon outdoors, either measured directly or inferred from daughter measurements, is about this factor lower than that indoors. However, the ranges may overlap. Work worldwide supports these conclusions.

The airborne radon and daughters from sources such as a uranium tailings pile became a source of considerable concern beginning in the 1960s. Concentrations of airborne uranium, radium, and radon were measured. None were of immediate dosimetric significance. Those from uranium mill tailings did not carry very far, falling by a factor of ten in 1 km. Water can carry the radium and radon much farther (more in chapter 11).^(a)

Much of interest to meteorologists has come out of these widespread measurements, but that is beyond our scope for now.

(a) Recently, there have been measurements of radon and radon daughter levels in caverns frequented by the public. An example is work in Howe Caverns by Seymore, Ryan, and Corelli (1980) at Rensselaer Polytechnic Institute in Troy, New York. The levels ranged from 0.008 to 0.25 WL with radon concentrations from less than 1 to 32 pCi/l. Since neither the public nor employees are in the cavern for extended periods, these levels were considered of no health concern.

C. Amounts in Water

Hursh et al. (1965) quote measurements of radon in natural waters from various parts of the world. Whereas the averages ranged from about 2 pCi/l to 30,000 pCi/l, with one very high value for springs in Beshtaugorsky, USSR (228,000 pCi/l), the maxima sometimes exceeded the average by factors approaching ten. It is interesting that natural waters with high ^{226}Ra content did not always have correspondingly high radon contents and vice versa. Thus, expected radon content cannot be arrived at by calculation from the radium content of water.

UNSCEAR (1977) reports that radon concentration in water used from private and communal wells frequently exceeds 20 pCi/l, and as much as 1,000 pCi/l is not uncommon. Water from thermal springs like Badgastein (see section VIII) may average 40 nCi/l (40,000 pCi/l). Open-air radon concentrations of about 1 pCi/l and indoors of about 10 pCi/l may arise from use of such water. When we remember that the original occupational standard for radon was 10 pCi/l, these values are not trivial, especially if there are other carcinogens in the environment.

D. Significance

UNSCEAR concludes that absorbed doses arising from inhalation of radon decay products under average natural conditions may be 160 mrad/yr to the segmental bronchioles, 30 mrad/yr to the whole lung, plus another 30 mrad/yr to terminal bronchioles, and 4 mrad/yr to the whole lung from the decay products of thoron. The total annual exposure of lung from all sources, both external and internal, is about 110 mrad/yr. The contribution of the radon daughters is thus over a quarter of the total, perhaps a third in some instances. In the case of the tracheobronchial tree, the total dose from natural background sources is about 200 mrad/yr, of which a substantial portion, on the average, is due to radon daughters. Thus, in terms of finding the contribution to dose, the work on naturally occurring levels of radon and radon daughters has been well worth doing. At present, we do not attach major biological significance to these doses and dose rates. The interpretation depends upon the models chosen for dose-effect relationships. However, they are close enough to significance over the lifetime of man to make us glad that we know approximately what they are. They are neither so trivial that they can be neglected, nor of clearly demonstrable biological significance. More studies are clearly needed.

E. Recent Events

Recently, an entire issue of the journal *Health Physics* was devoted to a series of papers on the measurement and possible significance of exposure to radon and its daughters indoors (Nero and Lowder 1983). The contents of this issue are given as note 1 at the end of this chapter. The growing emphasis on population exposures to radon and radon daughters is evident in these and even more recent publications.

The theme discussed above has been enlarged upon considerably in very recent symposia and publications. We have already encountered the "Specialist Meeting and Its Assessment of Radon and Daughter Exposure and Related Biological Effects" held in Rome in 1980 and whose proceedings were published in 1983. The table of contents of this symposium, note 2 to this chapter, shows the growing interest in indoor exposures to radon.

XI. Summary and Commentary

This chapter begins with the centuries-old malady afflicting certain miners in central Europe and ends with the present-day view that indoor concentrations of radon and its daughter products may constitute the largest single source of naturally occurring radiation.

Like radium, radon has been used for many years in therapy of cancer. This was accomplished by the preparation of radon "seeds" that could be placed close to an area, usually cancerous, requiring treatment. As with radium, it was the penetrating "hard" radiation that was important. In this case, it came from some of the decay products of radon, not from radon itself, which is an alpha-particle emitter. Also, like radium, radon has been used internally as a therapeutic nostrum for its alleged "stimulative" effects on various body processes. For this, the primary sources have been the large therapeutic spas. True benefits from these are hard to prove. True benefits from radon seeds are well known.

Our principal consideration is again the untoward effects of this naturally occurring series of radionuclides. In the mining of uranium, there is always radium present and thus radon and its daughter products. The tortuous path from complete mystery to a proven relationship between radon-plus-daughter-product exposure of uranium miners and lung cancer is a central theme of this chapter. The problem of the uranium miners is, of course, not uranium at all; it is principally the daughter products of radon. The proper characterization of the role of the daughter products has added further complexity to the already complex problem of bringing causation to the door of radon. The chapter reviews these in some depth.

The epidemiology of uranium miner populations began in the central European mines but did not become acceptable until relatively recently. We review this epidemiology with special emphasis on the work done in the Colorado Plateau area of the United States, the studies in Czechoslovakia, and, to a lesser extent, Canada, Sweden, etc. A central problem to the epidemiology has been dosimetry. The problems of establishing the radiation dose from radon and its progeny have been much more severe than in the case of radium. They even required the devising of a special unit—the working level and its time derivatives, working level month and working level year. The genesis of these units, their need, utility, and problems are reviewed in the chapter.

No institution can be singled out as being a mecca for dosimetric and epidemiologic studies with radon. In the United States, the U.S. Public Health Service, the state health departments, the AEC's Health and Safety Laboratory, and scattered university groups played central roles, primarily in the study of the miners and their environment.

As with radium and uranium, a large experimental program with animals was needed to complement and supplement the efforts surrounding human exposures. Centers for this work have been the groups at the University of Rochester Atomic Energy Project, Pacific Northwest Laboratory, and, to a lesser extent, Argonne National Laboratory. In Europe, much experimental work was done in France and Germany; the work extending back many decades in Germany. There have appeared to be many puzzling differences between the results of animal experiments and the findings in the uranium miners. Most of these have now been explained, or new, less-conflicting data have been gathered by better techniques and with better animal strains and husbandry. Yet, it still seems clear that something is different between the animal exposure situations and mining

(or milling) experience. Part of it may be due to secondary agents in the mine atmospheres. The work at Pacific Northwest Laboratory concentrated on adding adjuvants such as cigarette smoke, uranium ore dust, diesel exhaust fumes, and the like. However, the results did not demonstrate effects as large as were necessary to explain the differences. We are thus left with the provisional conclusion that the mechanism, type, and site of origin of the lung cancers in man may be different from those in the animal populations studied. This may or may not be resolved in the future. Exposures of man are now drastically lower, and many fewer cancer cases attributable to mining may, fortunately, occur.

The spas and "therapeutic" mines are sources of interesting information, and this is reviewed. However, except for characterization of the concentrations of radionuclides present and the associated dosimetry, these studies have not yielded acceptable epidemiology that compares in any way with the careful and relatively extensive analyses of the populations of miners.

The current concerns about population exposure arose partly from the presence of mill tailings in construction materials, the location of phosphate mines in areas with high radium and radon contents of the strata, and the much tighter sealing of homes and buildings for energy conservation. These are discussed briefly. While currently something of a cause célèbre, the true distribution of unusually high air concentrations of radon, and its daughters indoors, the numbers of people exposed, and the possibility of significant biological effects must await more detailed work for a satisfactory evaluation.

Capsule Chronology

Polonium

- 1898** Discovery of polonium, the first radioactive element to be separated from its ores (M. Curie).
- 1924-1938** Animal work by Lacassagne in France.
- 1930s** Chemistry worked out.

WORLD WAR II

Metallurgical Laboratory (Chicago) studies of distribution and excretion, later toxicity relative to radium.

University of Rochester studies of behavior of ^{210}Po after injection, inhalation, ingestion, skin absorption, etc.; biological effects and toxicity relative to plutonium and radium. Includes injection of a few hospital patients.

Manufacture of large quantities of polonium at "Dayton Project." Use in initiator for early nuclear devices. Biomedical research begins when the Dayton Project becomes "Mound Laboratory" at the end of the war.

POST-WORLD WAR II

- 1947-1964** Continuation and expansion of basic biochemistry, solution chemistry, physiology, and pathology at University of Rochester. Many varieties of cancer induced.
- 1948-1960s** Active biomedical program at Mound Laboratory (Dayton, Ohio).
- 1950s** Expansion of MED work on polonium at Chicago (M. Finkel, Argonne National Laboratory). Mostly relative toxicity, acute toxicology, and long-term effects.
- 1951** Effect of BAL on excretion and tissue distribution of polonium (Hursh at Rochester).
- 1956** Moyer monograph on polonium published (AEC Monograph, TID-5221).
- 1950s-1970s** USSR work on polonium published and translated at intervals. Summarized in 1971 and 1972.
- 1960s** Polonium studied in the arctic food chain (see also chapter 15).
- Mid-1960s** Interest develops in polonium in cigarette smoke as possible causative agent of lung cancer in smokers.
- 1964** Rochester work summarized as supplement to *Radiation Research*. Includes functional changes (Stannard, Casarett, and colleagues).
- 1964 et seq.** Interest in polonium excretion as a measure of radon exposure in uranium miners.
- 1972-1974** Polonium studied in marine algae (Folsom, Hodge, et al., Scripps Institution of Oceanography).
- 1973** Metabolic ward studies (Holtzman, Argonne National Laboratory).
- 1974 et seq.** Harvard studies of polonium in lung (Little and Kennedy).
Lung cancer produced in hamster.

Thorium

- 1899** Radioactive gaseous emanation from thorium described (Rutherford).
- 1900** Thorium-234 discovered (Crookes).
- 1905** Thorium-228 discovered (Hahn).
- 1907** Ionium (thorium-230) discovered (Boltwood).
- 1900 on** Use in gas mantles as thoria. Later as radiopaque medium.
- 1912-1940** Work in many countries on effects of thorium on a variety of organisms from unicellular to mammalian. Largely looking for chemical toxicity-as a rare earth, but some work with isotopes of higher specific activity. Production of sarcomata in animals shown with colloidal thorium dioxide (Thorotrast) in the 1930s.

WORLD WAR II

Mostly a silent period in biomedical work except concern for Thorotrast patients and thorium workers in gas mantle and metallurgical factories. Use as a nuclear fuel considered, and a small amount of work carried out on its toxicity, largely chemical, at Rochester.

POST-WORLD WAR II

- 1946, 1947** Tracer work at Berkeley published (Hamilton and Lanz). Done under Metallurgical Laboratory auspices during war.
- 1950 et seq.** Biomedical work with thorium at Western Reserve University.
- 1952** Importance of carriers and concentration demonstrated (Scott at Rochester).
- 1957** Thorotrast metabolism studied in man (Hursh at Rochester and Looney at Bethesda).
- 1958** Boone studies at Los Alamos (ionium).
- 1958-1969** Unraveling of metabolism of the seven thorium isotopes in man (Argonne National Laboratory and MIT).
- 1959-1960** Chemical toxicity of "natural thorium" (Downs, Hodge, and Thomas at Rochester). Rochester conference.
- 1959** Special curie for thorium proposed.
- 1960s** Thorium isotopes enter the Utah beagle experiment.
Reports throughout the 1960s and 1970s. Complex dosimetry worked out.
- 1960s** USSR work reported in a book by Letavet and Kurlyandskaya and reviewed by Moskalev.
- 1961** Thomas studies at Rochester.
- 1960s-1980s** Thorotrast work continues in laboratories and clinics in many countries.
- 1963** Inhalation experiment at Rochester (Boecker).
- 1966** Survey of thorium workers (Albert).
- 1968-1979** Several symposia on Thorotrast.
- 1971** Thorium-228 tops the list in producing osteosarcoma in the Utah beagles.

1974 Special curie for uranium and thorium abandoned. Suggested that "natural thorium" does not have a constant composition, and the term should be discarded (Hursh, NCRP).

1975 et seq. Effort concentrated on Thorotrast cases and animal experiments to delineate role of chemical toxicity in effects seen.

Thorium work with beagles at Utah completed.

Thorium epidemiology of factory workers begins.

Chapter 4

Polonium and Thorium

Overview

This chapter describes, separately, some of the more cogent biomedical research activities and health effects noted with the last two of the important naturally occurring radionuclides: polonium and thorium (see preface to this chapter).

As we saw in chapter 3, two of the most significant radionuclides in the radon decay chain, from the standpoint of health effects, are isotopes of polonium. Therefore, in a sense it can be said that the radon daughter problem is to a significant degree a polonium problem. However, the isotopes of most importance in the radon decay chain are of such short half-life that they cannot be studied in isolation from the other daughter products. Therefore, the biomedical research with polonium has used primarily ^{210}Po . This isotope has a 138-day half-life. Although it is a member of the radon decay chain, it is blocked from significant effect in reasonable time by the 21-year-half-life, ^{210}Pb , which precedes it. Polonium-210 was the predominant isotope isolated from radium by Madame Curie. It has been prepared more recently by neutron bombardment of bismuth.

Polonium differs greatly from most of the other alpha-particle-emitting radionuclides, both natural and artificial, in that it deposits mostly in soft tissue. It does not deposit in bone to any appreciable extent, although it may be produced in situ by the decay of ^{210}Pb already present in bone. Polonium has a strong affinity for the red blood cells and forms radiocolloids with ease. It is easily carried to tissues of the reticuloendothelial system (RES) with resultant high doses to spleen and liver. Much is also deposited in kidney as a result, in part, of its carriage in blood, and in part its fairly ready passage into the kidney tubules.

Since its degradation product is not radioactive (i.e., stable lead), and ^{210}Po is fairly readily obtained in high purity, biomedical research with it has provided an opportunity to study the effects of alpha radiation in comparative isolation from other radionuclides. The chapter reviews the early work with polonium by Lacassagne in France, the rather concentrated research devoted to it by the Manhattan Engineer District (MED) laboratories during World War II, the further work at these installations in the postwar period, and the recent notions that naturally occurring polonium in and on tobacco leaves may play a key role in the generation of lung cancer in cigarette smokers.

Biomedical research with thorium in its various forms is far more complex than that with polonium. Not only is the thorium series itself complex, but thorium isotopes of significance occur in other series (see preface to these four chapters). It deposits readily in bone, but it also forms exceedingly insoluble complexes in other tissues. Also, because of its low specific activity, there is opportunity for chemical toxicity in addition to radiation effects, although this is a relatively minor consideration compared to natural uranium. There is a significant worker population that has used thorium in various forms. The epidemiology of these populations is just beginning to be addressed and is described briefly in this chapter.

Probably the most significant exposures of humans to thorium isotopes have come from a radiopaque medium called "Thorotrast." This colloidal preparation deposited essentially permanently in the liver and other RES elements. While the involved thorium isotopes are basically only weakly radioactive, the long periods of exposure led to significant doses to many patients. Liver tumors have appeared in the several populations involved. These populations, both in the United States and abroad, are considered in the chapter along with the factory populations and the fairly extensive amounts of animal research. Considerations of thorium in the environment are put off to the sequence in chapters 11-15.

Prologue

Before launching into the discussion of polonium and thorium, it should be noted that, while these are the last two of the naturally occurring radionuclides we will consider in any detail, there are others. These are frequently referred to as "nonseries" radionuclides. Most of them have little toxicologic significance in the amounts normally seen in nature. Only through the activities of man, e.g., the production of ^{14}C and ^3H in nuclear reactions, do concentrations of these reach potentially significant levels. We will hold their review for later chapters. These "nonseries" radioisotopes are discussed briefly in the preface to these four chapters on naturally occurring radionuclides and are listed there in table PN-1.

The two elements considered here, polonium and thorium, occur as steps in some of the series as outlined in the preface.

Polonium presents a relatively straightforward problem compared to many we have considered thus far. By contrast, thorium isotopes present very complex problems and many dilemmas that research to date has only partially solved.

Part A. Polonium

I. Introduction

Polonium (element 84) was the first radioactive element Madame Curie separated from pitchblende. As is well known, she named it after her home country, Poland. It has twenty-five isotopes from mass number 192 to 218, all of them radioactive. As will be seen from table 4.1, most of the isotopes have very short half-lives. Only 208, 209, and 210 have half-lives sufficiently long to be of interest for experimental toxicologic research, although 214 and 218 are of significance in the radon daughter problem, as we saw in chapter 3. Of these isotopes, ^{210}Po is by far the most commonly encountered and is the one worked with

TABLE 4.1. Polonium Isotopes and Their Nuclear Properties

Isotope Mass	Mode of Decay		Alpha Energy (Mev)	Method of Production*
	Half-Life	Emissions		
192	0.5 s	α	6.58	Bi + p
193	4 s	α	6.47	Bi + p
194	13 s	α	6.38	Bi + p
195	30 s	α	6.26	Bi + p
196	1.9 m	α	6.14	W + Ne

biomedically. With an almost pure alpha emission and a half-life neither too long nor too short, chemical properties resembling the rare earths and quite different from those of radium and plutonium, ²¹⁰Po has been much used as a source of alpha particles for many purposes. Furthermore, it is the last radioactive member, and a significant one, of the radium series as it occurs in nature.

In this chapter, we will be referring so regularly to the 210 isotope that we will not give numbers unless other isotopes of polonium are involved. The 210 isotope decays with a 138-day half-life to a stable lead isotope (^{206}Pb), and the decay has virtually no contamination with beta or gamma radiation. (One decay in 10^5 is a gamma of low energy, 0.8 MeV, and there are still lower-energy x rays.) In the earlier days of describing the radium decay series, ^{210}Po was called "Radium-F" and ^{206}Pb was called "Radium-G."

Polonium has been used extensively as an alpha-particle source in the production of neutrons by its reaction, for example, with beryllium. Many large sources were prepared before plutonium became available in sufficient quantities to supplant it. In fact, it was the alpha source in the neutron-producing initiator for at least the first generation of atomic weapons and was produced in large quantities during the MED days. Because of the relatively short half-life, production had to continue even though the weapons were not used. A project known as the Dayton Project, operated by the Monsanto Chemical Company in and around Dayton, Ohio, was engaged in the production of ^{210}Po for neutron sources.

Polonium has also found wide application in static eliminators for many commercial processes, such as paper plants where the accumulation of static electricity on moving machinery can lead to disastrously erratic behavior of the material passing through. But it has proven difficult to contain the polonium on the eliminator bars, and several cases of considerable contamination have been reported. (See for example Robertson and Randle 1974.)

Other instances of contamination have resulted from breaking of alpha or neutron sources containing polonium. (See for example Callihan and Ross 1952; Scott and West 1975.) Also, polonium has a very marked tendency to "creep" if left in the open in either solution or solid form. A laboratory that was clean on Friday evening may be found widely contaminated with polonium alphas on Monday morning from a source left in the open on a laboratory bench, or even in a hood.

Despite these instances and others, direct contamination of man with ^{210}Po is a rare bird in comparison with radium, uranium, and the radon daughters in uranium mines^(a) reviewed in the previous chapters. Primary reasons for interest in it lie in its research uses and potential for contamination and the consequent need for information upon which to base permissible exposures.

II. Early Research

Polonium has long been a very useful tool in physics and physical chemical research because of its energetic and almost pure alpha-particle emissions. For the same reason, it was a good candidate for use in biomedical research. But only one major effort took place in the years before World War II. This was work by Lacassagne and colleagues in France, results of which were published over the years 1924 to 1938. The papers were mostly in the *Comptes Rendues* and *Journal de Radiologie et de l'Electrologie*, and were nicely summarized by

(a) It should be noted, however, that the principal radiation dose from radon daughters is contributed by two polonium isotopes, ^{218}Po with a 3-min half-life and ^{214}Po with a half-life of 104 sec. Thus, the radon daughter problem is partly a polonium problem, and this adds impetus to knowing its biomedical behavior (chapter 3).

Silberstein in a volume of the National Nuclear Energy Series (NNEs) (Silberstein 1950). A smaller effort was reported by Fernau and colleagues (1913).

Lacassagne used rabbits primarily and injected the polonium in dilute HCl. His work made it apparent that polonium was biochemically and pharmacologically very different from radium. This was no surprise, for its chemical characterization (e.g., Haissinsky 1961) had already indicated that it was different. The principal differences are its more generalized distribution among tissues in contrast to the tendency of radium to localize in bone; its easy hydrolysis to form insoluble colloids, which are taken up by organs of the reticuloendothelial system (RES); and its concentration in kidney cortex and interstitial tissue of the testes. Some pioneering autoradiographic work helped with these localizations.

Kidney and spleen had the highest concentrations at early times. Spleen rose to be over tenfold higher than the kidney at about sixty days, then fell back somewhat. Elimination was fairly rapid with a biological half-life of about forty days.

A serious problem with Lacassagne's work was the low recoveries from tissues and excreta. Combined, they did not exceed 12% of the dosage thought to have been administered. This led Lacassagne to postulate that large portions of the dose were excreted through lungs and skin, but no measurements of these were recorded. A more likely explanation, as Silberstein (1950) pointed out, is incomplete plating of the polonium on the silver foil used for measurement. The solutions contained fat and solids, which could easily have interfered with the plating. Another possibility is that the dose actually administered was much lower than thought to be, because of the distressing tendency of polonium (and many other radioelements) to deposit on glass surfaces. The technique of "dummy injection," so commonly used in radioisotope research from the 1940s on, is not mentioned in this early work.

Despite the technical problems of recovery, it is impressive to note how well the relative concentration of polonium in major organs tallies with later work.

Finally, it is clear that the statement that polonium is more or less uniformly distributed is true only in a relative sense. While there are not the striking contrasts seen with the bone seekers, there are manifold differences between the highest and the average tissue content.

III. Polonium Research During World War II

A. The Setting

The principal sites of biomedical research on polonium under the Manhattan District were the Metallurgical Laboratory at Chicago, where work started rather late in the war years, and the University of Rochester Project, which engaged in work on the comparative toxicology of three important alpha emitters (polonium, plutonium, and radium), plus some very necessary studies of the metabolism (i.e., distribution and excretion) of polonium and radium. The *raison d'être* was partly the establishment of relative toxicity ratios to help set exposure standards for plutonium (see chapters 6, 7, and 16). But there was a need also for much more information on ^{210}Po itself, for it was being prepared in considerable quantities at the Dayton Project. Therefore, the work, especially at Rochester, delved fairly deeply into the behavior of polonium in biological systems in its own right, as well as comparative toxicity studies.

It is doubtful if many of those engaged in the work knew the reasons for doing it. Security was tight. The very existence of the Dayton Project was not generally known, even though it managed to contaminate the former Runnymede Playhouse in a fine residential suburb of Dayton so badly that it had to be demolished in February 1950. Also, it transformed the old Bonebrake Theological Seminary, leased by Monsanto, so thoroughly that extensive renovation and decontamination were needed to return it to the Board of Education in 1950. In fact, at its peak, the Dayton Project was using twenty buildings around Dayton for research and the extraction and purification of polonium from materials of various origin, from radium residues from the Port Hope, Ontario radium refinery to irradiated bismuth from the Clinton Reactor (Moyer, Gnagey, and Rogers 1956). Records as to the number of workers are not easy to find, but there were clearly enough to make a full-blown biomedical investigation worthwhile for the setting of standards. Until the very end of the war, when the Dayton Laboratory began to develop a biomedical research group of its own, most of the needed data and advice for standard setting came from the Rochester Project, particularly from William F. Bale, Robert Fink, and, toward the end of the war, John B. Hursh.

The code name for polonium in the MED days was "Postum."^(a) Only a few in the very top echelons were supposed to know its translation. However, anyone with a good chemistry background should not have had much difficulty in translating a code name whose first two letters spelled out the chemical symbol for the element, especially if they also knew it was an alpha emitter with amphoteric properties. (The code name "Tuballoy" for uranium was probably a better choice for a cover.)

Nevertheless, postum or polonium, or just "solution-x," the Rochester and to a lesser extent the Chicago group took up where the Lacassagne work left off. This is the subject of the next section.

B. Distribution and Excretion

1. Methodology

The results of over five years of work at Rochester were made available in the usual internal reports, which were issued as often as monthly. For our purposes, we can rely primarily on the volume in the NNES series edited by Fink (Fink 1950) and the Argonne National Laboratory (ANL) reports after the war.

One of the first areas of attack was analytical technique. Polonium plates spontaneously on a number of metals, but also on nearly every other surface at hand. The Rochester group spent much effort on getting a good digestion procedure that would oxidize the troublesome interfering substances, particularly fat, and present a clear solution that could be set up for plating on silver foil with confidence. An entire chapter in the Fink volume is devoted to details of the general methods (Gorham et al. 1950).

Dry ignition was precluded because of the high volatility of polonium at elevated temperatures. The best recoveries were obtained with a mixture of 70% perchloric acid plus concentrated nitric acid. This had the disadvantage of extreme instability in the presence of fat. This produced some of the explosive oxides of chlorine, and there were accidents. But no better procedure appeared,

(a) The corresponding name for plutonium was "Product."

and the danger of explosion was kept as low as possible by always using relatively small aliquots and multiplying the number of digestions if necessary. (A whole rat carcass, for example, would be divided into several fractions, or special precautions would be taken in the heating process.)

By constant attention to detail, the recovery in the plating process was improved markedly, even approaching 100%. The set-up for plating is described with diagrams in the cited chapter. This basic system was adapted to the large numbers of samples needed in the routine biological monitoring at various sites.

Even with the best technique, it was not possible to prepare injection solutions by simple dilution and be sure of their polonium concentration. Therefore, the technique of the "dummy injection" was routinely applied. This amounted to repeating the "injection" immediately after the real injection, but emptying the contents of the syringe into a known volume of fairly strong acid. The measured content of this solution became the administered dose, no matter what the intended dose was. Fortunately, so long as the solution was kept strongly acid, the polonium did not precipitate or plate out. But as soon as the pH rose toward neutrality, the plating out and colloid formation began.

For the war work, the stock solution was neutralized just before injection with moderately strong alkali. As we will see in the postwar work, this almost inevitably produced at least some insoluble complexes. We can be sure that the injection solutions contained from some to considerable amounts of insoluble complexes and radiocolloids. This must be kept in mind as we review the distribution and excretion results.

A special glass metabolism cage was built in sizes suitable for rats or rabbits to separate urine from feces. Much work was done to perfect both their design and surface preparation. (Plastics were not yet available. Stainless steel, used so much in the Plutonium Project, was in short supply and might not have worked well anyway.)

2. Animal Studies

The animal studies on distribution and excretion of polonium involved, at Rochester, intravenous and subcutaneous injection, oral administration by gavage, and inhalation of volatilized polonium in the white rat, absorption through the skin of the mouse, and intravenous injection in the rabbit (Silberstein et al. 1950). At Chicago, the studies were by intravenous injection in CF1 mice (Finkel et al. 1949). The bulk of the work was done by intravenous injection at both laboratories, with other routes primarily used for a quick comparison.

At Rochester, detailed measurements were made of both urinary and fecal excretion with daily measurements out to as long as three hundred days. The animals (rats) received from 1.5 to 30 $\mu\text{Ci/kg}$ body weight. Fecal excretion exceeded urinary by factors up to ten at all times. The fecal excretion after intravenous administration was largely via the bile, as testified to by an experiment in which the bile duct was ligated.

Figure 4.1, taken from the Fink volume, illustrates the kinetics of loss. Retention was, of course, the inverse of this relation. The half-time was, on the average, about twenty-five to thirty days on the basis of percentage of dose, about forty-five days on the basis of microcuries lost per 100 μCi injected (see figure 2.7 in Fink 1950, p. 52). Obviously, polonium is lost more rapidly than many of the bone-seeking elements.

FIGURE 4.1. Excretion of polonium by the rat following intravenous injection. (Redrawn from Fink 1950, p. 51.)

The distribution among the tissues can be best described by reproducing two diagrams from the Fink volume. Figure 4.2 shows the percentage of dose per gram at four selected times after intravenous administration to the rat. Spleen, as an active organ of the RES, has the highest content at all times. Kidney, while lower, is surprisingly high for not being an RES organ.

In figure 4.3, the information is presented as percentage of body content per gram of tissue. This mode of expression gives a better view of shifts in tissue distribution with time since it combines the factors of decay and elimination that affect the perspective, at long times especially.

After intravenous administration, the two modes of expressing the data are remarkably similar. The primary exception is the climbing of red blood cells as a fraction of the body burden, a subject we shall return to when considering the postwar work.

The distribution after intravenous administration in the rabbit was somewhat different from what it was in the rat, with higher concentrations in kidney and testis, for example, but lower concentrations in spleen, pancreas, and thymus. The rabbit kidney concentration was four times higher than any other tissue. Perhaps because of this, urinary excretion was much higher in the rabbit than in the rat.

FIGURE 4.2. Percent dose per gram in rats after intravenous administration of polonium chloride. (Redrawn from Fink 1950, p. 54.)

FIGURE 4.3. Percent body content per gram in rats after intravenous administration of polonium chloride. (Redrawn from Fink 1950, p. 60.)

After subcutaneous administration, there was a higher kidney content and higher urinary excretion for about one day. Otherwise, the distribution and excretion were quite similar to that after intravenous administration.

There were some surprises after oral administration. There was the usual high fecal excretion associated with a relatively poorly absorbed element (less than 10% absorption), and an increase in urinary excretion, which is always hard to interpret because of possible contamination of the urine from feces. But there were other significant differences. The concentrations in RES tissues were relatively lower than after intravenous administration, while the concentration in red cells was markedly high.^(a) Indeed, the red cells show the highest concentration found in any tissue, accounting for from one-fourth to one-half of the total amount in the body at ten days after gavage.

The authors speculate briefly that there must be an important difference in the chemical state of polonium entering the blood by absorption from gut compared to that introduced directly into the blood stream.

The inhalation studies involved fairly elaborate equipment for bringing air laden with polonium volatilized from a hot wire to animals. Volatilization is easy because of the low temperatures at which polonium volatilizes. The exposures were done either singly, with only the animal's snout in the air stream, or in groups of fifteen to twenty rats in 12-in.-diameter glass jars. Careful measurements were made not only of the initial deposition in lung, but of the transfer to other tissues. As expected, the lung had the highest concentration initially, and it fell rapidly in the first two days. Not fully expected was that some polonium appeared to settle in the lung for a more extended stay.

Autoradiographic studies showed rapid clearance of polonium from the bronchial walls with patches of dense activity further into the alveolar tissues. Thus, despite being a "relatively soluble" substance, the polonium was clearly aggregating either through physical-chemical processes or by the action of phagocytes.

The amounts after inhalation, as fraction of the body content, in other important tissues such as spleen, kidney, liver, lymph nodes, etc., were in the same range or a little lower than by other routes. There was a small indication of increased amounts in red cells.

Twelve experiments were done to observe the absorption and distribution of polonium placed on the skin of the mouse. The solvent was saline, and absorption was very low. Absorption from organic solvents was not tried.

The Chicago (Argonne National Laboratory) work with polonium began toward the end of the war. As we will see in chapters 7 and 8, it was part of a large-scale experiment on relative toxicity of alpha emitters. But there were special studies made of polonium in its own right.

A short summary of distribution and excretion in the CF1 mouse is given by Finkel et al. (1949) in an ANL report and by Finkel and colleagues in a published paper (Finkel et al. 1953). Total amounts in organs are shown in figure 4.4A and concentrations in figure 4.4B.

Spleen and kidney maintain the position seen in the Rochester experiments with the rat, but with spleen even higher. For example, at 120 days after intravenous injection, the whole spleen contained 97% of the polonium. The ovaries contained significant amounts on a concentration basis. This led the authors to

(a). This elevation persists over long periods, even beyond the life span of the red cell in the rat.

FIGURE 4.4A. Distribution of retained polonium in the CF1 mouse. The scale is μCi in organ $\times 100$ divided by μCi in total animal. (Redrawn from Finkel et al. 1953. Reprinted with permission of The Williams & Wilkins Co., Baltimore, Maryland, copyright 1953.)

speculate on the possibility that ovary might be the critical organ on the basis of its radiosensitivity. However, it remained for postwar work to unravel the possible importance of either ovary or testis in polonium toxicity.

Overall retention in the mouse was comparable to that seen in the rat.

In much of the Argonne (and Rochester) work, microscopic localization in tissue structures was followed by autoradiography as well as by radiochemical analyses.

3. Human Studies

Information on the distribution and excretion of polonium was obtained in humans by experimental injections in hospital patients and by analysis of the occasional accidental contamination.

At Rochester, five hospitalized patients in the terminal stages of lymphatic cancer or leukemia were given intravenous (four patients) or oral (one patient) administrations of small amounts of ^{210}Po . The results are described in chapter 3 of the Fink volume (Fink 1950). The problems of polonium loss in preparing a sterile solution, the inadvertent use of glass urinals, and other technical problems are given in sufficient detail to evaluate the results.

The subjects were:

1. male, generalized lymphosarcoma, i.v. injection of 22.6 μCi at pH 7.6;
2. male, acute lymphatic leukemia, i.v. injection of 11.3 μCi , pH not given;
3. male, chronic myeloid leukemia, i.v. injection of 12 μCi at pH 7.0;
4. female, chronic myeloid leukemia, i.v. injection of 8.6 μCi at pH 7.0;
5. male, chronic myeloid leukemia, oral administration of 18.5 μCi in 2 ml of 0.3 N acid with tap water.

Case 2 died on the sixth day from his far-advanced cancer, and tissues were obtained at autopsy for measurement of polonium concentration. Other subjects lived for longer periods, and excreta were collected for as long as seventy days in Case 3. No other tissue samples became available in this series.

A comparison of relative polonium concentrations in the tissues of Case 2 to rat and rabbit indicated much more in bile and liver, a little less in kidney and in blood cells, and the other tissues were not markedly different from the animal data. Since the information for man came from only one case, very ill, and the polonium was present for a very short period, the Rochester group felt constrained to say no more than that the tissue distributions in man "indicate fairly close similarity between the human, the rabbit and the rat" (Fink, p. 130). The same applied to the excretion results. However, it did appear that the polonium concentration in blood fell more slowly in human plasma and more rapidly in human cells and whole blood than in the rat.

The one case given polonium orally indicated that uptake from the gut was less than 10%. Excretion was largely by the feces as in the rat, remaining at over ten times the rate in urine, even as long as 230 days after the administration. After intravenous doses, it was always from ten to twenty times above urinary excretion.

Kidney clearance of polonium was estimated from the collection of excretion data on these cases. It was surprisingly low in comparison with similar metals such as arsenic and selenium.

Absorption through human skin did not exceed 2% of the dose per day. Red cell uptake in vitro was slower than in vivo.

Comment on Human Studies. Like the human studies on uranium described in chapter 2 and those on plutonium to be cited in chapter 7, these experimental injections would be almost impossible now. The published results do not delve into matters of informed consent. But it seems likely that these individuals knew their prognosis well and if asked would have been glad to help out with the war effort.

Confirmation of the experimental work in humans with information from cases of accidental exposure did not take place until postwar, partly because of the tight security on information concerning polonium.

C. Toxicity of Polonium

1. Acute Effects—Lethality

Toxic doses of polonium were given to rabbits in the very early experiments of Fernau and colleagues (cited in the Fink volume, chapter 7) and of the Lacassagne group cited there also. Chapter 7 of the Fink volume both summarizes these works and gives much detail. By translating the electrostatic units used by Lacassagne to microcuries, Boyd, Silberstein, and Fink (1950) estimated acute lethality at about 50 $\mu\text{Ci/kg}$ for twenty days. By interpolation of their graph (figure 7.2 of the Fink volume), the similar figure for thirty-day lethality would be about 30 $\mu\text{Ci/kg}$. These cannot be regarded as true LD_{50} ^(a) values because of the paucity of data, but they give the general range of effectiveness.

As a part of the large comparative study of polonium, plutonium, and radium at Rochester, discussed in chapter 7 of the Fink volume, Boyd, Silberstein, and Fink (1950) gives details of the polonium series. The comparative toxicity results were graphed as figures 7.14 and 7.15 in chapter 7 of that book. By a plot of mean survival time against dosage, Boyd calculates the LD_{50} for twenty days at 130 μCi per kilogram body weight in the pilot experiment.

The much larger "simultaneous study" (Fink 1950, chapter 8, especially Boyd and Fink, part 6) did not provide data that could be analyzed by formal procedures for the LD_{50} , but an approximation could be made from median survival times plotted against median dosages. Here median survival time of twenty days was associated with a median dosage of about 43 $\mu\text{Ci/kg}$. The similar figure for thirty-day median survival time was about 35 $\mu\text{Ci/kg}$. The authors give (in their table 8.9) 27 $\mu\text{Ci/kg}$ as the 50% lethal dosage of polonium for forty days. All of these are considerably lower than the figures derived from the smaller pilot experiment and are probably more reliable. Also, they agree better with the figures derived from Lacassagne's work with the rabbit.

The Chicago work by Finkel et al. places the LD_{50} , thirty days, of intravenous polonium in the CF1 female mouse at "between 30 and 40 $\mu\text{Ci/kg}$." The figure from their graph (figure 3, Finkel et al. 1953) is 36.5 $\mu\text{Ci/kg}$. Such agreement with the work on the rat may be fortuitous, but let us accept it at face value.

Because of the high specific activity of polonium, these acutely toxic doses represent minuscule weights. The 50% lethal dosage at twenty days is only 0.0096 $\mu\text{g/kg}$, and at forty days only 0.0060 $\mu\text{g/kg}$. Similar figures for ^{239}Pu are 1,320 $\mu\text{g/kg}$ and 860 $\mu\text{g/kg}$ and for ^{226}Ra they are 2,100 $\mu\text{g/kg}$ and 1,140 $\mu\text{g/kg}$. Polonium is obviously a much stronger candidate than plutonium for the title of

(a) The lethal dose to 50% of the animals.

"most toxic element known to man" in terms of acute lethality on either a weight basis or an activity basis.

2. Acute Effects—Pathology

The careful documentation of pathological changes in the Rochester experiments with radium has already been reviewed in chapter 1; those with plutonium are reviewed in chapter 7. The changes after polonium were so much like those after acute doses of whole-body x-radiation as to make any extensive description redundant. The testes and hematopoietic organs showed the most change in the pilot experiment (Metcalf, Casarett, and Boyd 1950). In the larger simultaneous experiment, detailed clinical observations preceded the presentation of pathology (see chapter 8 of the Fink volume). Reduction in spleen size occurred at lower doses of polonium than of plutonium or radium, while very few growth abnormalities occurred in liver. Detailed histopathology was done in this experiment and reported by Casarett, Metcalf, and Boyd (1950). Again the changes were principally manifested in gonads and hematopoietic organs. They involved hypoplasia, atrophy, and hemorrhage. The same types of change appeared in other organs but to a lesser degree. The authors considered only animals dying in periods up to one hundred days after injection and, thus, the work can be considered acute or subacute. Longer-term effects, including the development of cancer, will be described in later sections.

Formal hematology studies, as contrasted to pathology, were done for polonium only in the simultaneous experiment.

3. Long-Term Effects

In the Rochester work, the primary long-term effect studied carefully during the war was lethality out to 300+ days in the pilot experiment and to about 120 to 160 days in the simultaneous experiment. To a lesser extent, they report weight gain or loss. The comparative toxicity is taken up in detail in our chapter 7. Suffice it to say here that polonium persisted in being the most effective of the trio, polonium, plutonium, and radium. At 100 days, it exceeded radium by a factor of eighteen on a per microcurie basis, or 82,000 on a per microgram basis. At 300 days it was, however, only a factor of two higher than radium and the same as plutonium on an activity basis. This change in relative effectiveness, while quantitatively not fully reliable because of the small size of the pilot experiment, is seen also in postwar studies, which we will review presently.

The Chicago work on long-term effects was not reported until 1954.

IV. Research on Distribution, Excretion, and Effects of Polonium in the Post-World-War-II Era

A. Introduction

Postwar work on polonium followed two quite distinct pathways. The first, which is the subject of this section, was a continuation and extension to longer times and greater depth of the type of work done during the war, i.e., distribution, excretion, and effects of experimentally administered doses in animals. The second area concerned polonium in the environment, especially its presence in tobacco and its possible contribution to the genesis of lung cancer in people. This is the subject of section V.

Three American laboratories made the major contributions to the extensions of the war work: ANL, Mound Laboratory,^(a) and the University of Rochester Atomic Energy Project. In addition, a large effort was mounted in the USSR and the United Kingdom, and German laboratories entered on specific problems.

Production of polonium in large quantities declined markedly in the postwar era, and the work was thus less pushed by practical needs. Nevertheless, potential for large contaminations with polonium appeared in the proposed use of molten bismuth in some advanced design reactors.

The ANL work consisted essentially of completing the long-term mouse experiment and reporting it in an ANL report. The Mound Laboratory work considered distribution, excretion, and effects in both animals and man. Results were released primarily in Mound Laboratory reports, although there was a summary by Spoerl and Anthony (1956) as a chapter in the monograph edited by Moyer, Gnagey, and Rogers (1956)^(b) and a few open literature publications, particularly from the Atoms for Peace Congress. The Rochester work, while issued piecemeal as project reports, was gathered together in a single publication as a supplement to the journal, *Radiation Research* (Stannard and Casarett 1964),^(b) termed hereafter the "Polonium Supplement." The USSR work is available in the AEC Translation Series as a useful and succinct monograph (Moroz and Parfenov 1972a).

B. Solution Chemistry and Radiocolloids

The postwar work not only extended the periods of observation, went to lower dosage levels and chronic administration modes, but delved much more into the physicochemical reasons for the peculiarities of distribution and excretion uncovered. The first five papers of the Polonium Supplement dealt with the colloidal properties of polonium in solution, its binding to biological entities, particularly blood constituents, and the bearing of these on biological behavior. The Mound Laboratory looked at the association of polonium with blood as described in several quarterly reports and a publication by Campbell and Talley (1954).

Both sets of results showed that the polonium in the blood is associated primarily with the red cells, and in them it is attached to the globin portion of the hemoglobin molecule (Thomas 1964; Campbell and Talley 1954). Work on the behavior of polonium as a colloid (Morrow et al. 1964a; Thomas and Stannard 1964c) helped to explain its behavior in vivo (Thomas and Stannard 1964b).

(a) In 1945, the MED concluded that the Dayton Project should become a permanent facility to be operated by the Monsanto Chemical Company. The site for the new installation was on the edge of Miamisburg, Ohio, near the site of some ancient Indian mounds about twelve miles south of Dayton. On this basis, it was named "Mound Laboratory." Some biomedical work was probably begun even before completion of the new facility in 1948-1949. But all of the reports are sufficiently postwar that their review is more appropriate for this section of the chapter.

The new "Mound Laboratory" began by processing polonium for neutron and alpha sources. But in later years, it turned more to production of plutonium sources, especially ^{238}Pu as used in space vehicle power sources and other applications including biomedical ones. The Biology Division was disbanded sometime in the late 1960s, but Health Physics has, of course, continued.

(b) The tables of contents of these two monographs are given as notes 1 and 2 at the end of this chapter.

The markedly increased amount of polonium associated with red blood cells after oral administration seemed also to find a likely explanation. It appears that the form combining with hemoglobin in the red cell is essentially monomeric. The absorption from the gastrointestinal tract to blood is much more in monomeric form than after direct intravenous injection. Conversely, the polyatomic groupings, either present in the injection solution or formed by the rather sudden high concentration of polonium introduced intravenously, are picked up by elements of the RES.

Autoradiographic studies by Gallimore, Boyd, and Stannard (1954) confirmed the microscopic presence of large aggregates of polonium in cells and tissues after intravenous administration and traced their gradual dissolution with time. L. J. Casarett (1964a) showed that these aggregates were not present after oral administration. He pointed out also that aggregates, when present, were found principally in the alveolar walls of the lung, the Kupffer cells of the liver, the red pulp of spleen and other constituents of the RES. Nonaggregated polonium maintained qualitatively the same distribution, irrespective of the route of administration, whereas aggregated polonium distribution was quite sensitive to route of administration, form administered, and even the size of the dose.

Lanzola, Allegrini, and Taylor from the United Kingdom (1973) examined the subcellular distribution of polonium over periods of up to forty-seven days after various routes of administration. They conclude that it binds rather nonspecifically to protein, a conclusion also drawn by the Rochester workers from electrophoresis studies in vitro (Thomas 1964). The U.K. investigators found some evidence that the sulfhydryl group of cysteine may be an important binding site. They also suggest that at low concentrations, such as those attending occupational exposures at or below the maximum permissible level, the complexing agents in blood and tissues should be present in sufficient quantity to wipe out differences in form caused by different routes of administration. While logical, there has not been experimental verification of this point, since all the work we are reviewing was at doses well above the maximum permissible occupational exposure.

Feldman and Saunor (1964) worked out the filterability of polonium in the presence of various polycarboxylic and amino acids and concluded that in tracer concentrations any polonium carried in the blood in diffusible form would be bound to citrate (about 75%) and bicarbonate (about 20%), with the rest bound to other small moieties. Being physical chemists, they were especially unhappy with the lack of reproducibility in their preliminary work and turned to "homogenous pH adjustment" instead of bringing acid solutions to neutrality by adding droplets of strong sodium-hydroxide solution. The homogenous pH adjustment was achieved by operating in urea plus ammonium chloride, plus heat. Solutions prepared by this means showed little change in filterability at different polonium concentrations, while solutions prepared by the conventional method did show such an effect of concentration.

These phenomena led the editors of the Polonium Supplement to append a footnote to the Feldman-Saunor paper as follows:

Editorial Note: It is unfortunate that many long-term animal studies had been started, using older techniques, before the findings described in this paper were available. Refinements in solution preparation might have reduced the range of biological observations. Yet this is only conjecture, and it is equally likely that such refinement would have had little influence on in vivo results. Also in inhalation experiments, and in many experiments using other routes, the initial solution was

not neutralized before entry. Especially noteworthy is the fact that tissue distribution and excretion were not measurably different, nor was the range of values different after intravenous injections of acid solutions as compared to neutralized or partially neutralized solutions. Thus the total history of the solution before and after injection must be considered, as was pointed out by the authors in this paper, but large differences in biological end-point results may not necessarily follow any given variation of solution handling or history. In each of the papers that follow, the handling of the injection or exposure solution will be spelled out. (Stannard and Casarett 1964, p. 47)

There is no question but these phenomena are applicable, to some degree at least, to all work with injected radioisotopes. The history of the solution should be both known and controlled.

These phenomena, plus the possibility of differences between tracer levels and toxic levels of elements such as polonium, raise questions about the validity of details of some of the work done, both during and after the war. However, since we are interested in both, the question is not so much one of validity of results as careful scrutiny of the conditions before making broad generalizations or extrapolations. Very possibly phenomena such as these may underlie many instances attributed to "biological variability."

On the other side of the coin, it may be the unaggregated material that contributes most of the dose (L. J. Casarett, 1964a; Stannard and Casarett, 1964, p. 401). This fraction is less influenced by the many factors impinging upon it than the more spectacular aggregates.

Three paragraphs from p. 401 of the Polonium Supplement bear on these considerations:

An important contrast in physical state in vivo is seen by varying the route of entry. The larger aggregates characteristic of early times after intravenous administration do not appear in blood or tissues after oral administration. They are seen in the gut, however. Thus, the contribution of the large aggregates is entirely absent after oral administration except for the gut wall itself. After inhalation, aggregates can be found in lymph nodes, lung, upper respiratory tract, gut, or phagocytic cells, but almost never in other tissues.

In a sense the presence and behavior of these aggregates is analogous to the "hot spots" much discussed in work with the bone-seeking α -particle emitters. However, the aggregates do not persist as such for long. The source of "hot spots" is more referable to biological concentrating mechanisms—for example, concentrations of macrophages, "whirlpools" in the bronchiolar ciliary epithelium, and concentration in lymph nodes—rather than to processes at the submicroscopic level as alleged for the accretion of radionuclides in bone. Thus, the analogy may actually be of little significance.

Furthermore, even the apparent localization seen may contribute less to the total radiation dose than might be predicted from casual observation. L. J. Casarett points out that the single atoms or small groups of atoms, ubiquitously present in the tissue sections studied, are much less dramatically emphasized in the autoradiogram than the large aggregate. Careful track counts indicated that less than 20% of the total activity appearing in the autoradiogram was contributed by polonium in the larger aggregates. This was in tissues of an animal receiving "neutralized" solution intravenously and hence having a maximum of larger aggregates. Since the aggregates are disorganized within a few days in vivo, we must conclude that the "hot spot" problem is probably not of large significance, nor is this aspect of the physicochemical state of the entering solution the primary factor in determining dose distribution except during the initial hours after administration. (Stannard and Casarett, 1964, p. 401)

The work of Moroz and colleagues (1971, 1972) in the USSR also examines the importance of radiocolloid formation and reaches similar conclusions.

C. Distribution and Excretion

The principal centers of activity postwar were Mound Laboratory, Rochester, and the USSR.

Effects of the route of administration were examined in depth at both Rochester and Mound Laboratory (Davis and Stevenson 1954; Stannard 1964; Morrow et al. 1964b; Thomas and Stannard 1964a; Morrow and Della Rosa 1964; Berke and DiPasqua 1964; L. J. Casarett 1964a,b; Smith et al. 1961). The routes were intravenous, oral, intratracheal, inhalation, and a direct introduction into the isolated intestinal loop in the cat. While the rat was still the principal test animal, cats, dogs, and rabbits were included for spot checks.

On the whole, the differences among routes were not unlike those noted in the wartime work, but the experiments were much larger and longer in general.

One of the earlier postwar publications on distribution and excretion concerned inhalation of a polonium aerosol by dogs (Smith et al. 1961). The radioelement was inhaled on a sodium chloride vector aerosol, and the observations went to about 150 days. Over 60% of the inhaled polonium was deposited in the animal, mostly in the lung. It left relatively slowly, going down to 32% to 49% of the total body burden in lungs by thirty days, and thereafter leaving with a biologic clearance half-time of about thirty-six days. Lung content and excretion seemed to follow single-exponential-loss kinetics, while whole-body-burden loss required a two-phase equation. Curiously, the pelt increased temporally in content relative to other organs, and the polonium seemed to be in the hair follicles. This observation was never followed up.

A useful series of equations is given for calculating radiation dose, body or organ burden from blood or excreta contents.

The bulk of the distribution and excretion work employed the rat. A summarizing comment on the results of long-term studies at Rochester is given in the following excerpt from the summary chapter in the Polonium Supplement:

Long-Term Studies of Distribution and Excretion

To understand long-term biological effects, it was considered essential to study the pharmacodynamics of the radioisotope over equivalently long periods. Therefore, two massive experiments were undertaken; one concerned the fate of a single intravenous dose for as long as it could be followed (445 days), the other a multiple-dose regime carried for the life span of the animals.

The single-dose experiment demonstrated marked differences and some points of general similarity in metabolism of polonium in different organs and tissues as a function of elapsed time. In all tissues except testis there were two phases of loss—a rapid phase, sometimes exponential with time but frequently continuously variable with time, and a slower phase, usually exponential with time. But the duration of the rapid phase varied from zero to 300 days, whereas over-all half-times ranged closely about 30 days. The duration of the slow phase varied from 150 to 450 days with effective half-lives from 59 to 93 days. Obviously, such a range might allow a large variety of tissue retention patterns, and such is indeed the case. It was possible, however, to group the tissues under three major headings: group I, containing spleen, kidney, liver, lung, lymph nodes, bone marrow, and femur, which has a long rapid phase and thus a fairly rapid total loss; group II containing testis, skeletal muscle, and heart, which has a short rapid phase or none at all, a longer slow phase, and slower average loss; and group III containing blood cells, which held polonium most tenaciously of all tissues ($T_{eff} = 93$ days).

If biological loss only is considered, the differences in tissue binding are further emphasized. The retention half-time for liver is only 11 days, but it is 153 days for testis. The median half-time among tissues for polonium loss is 38 days, in good agreement with the values for the whole body and skeletal muscle.

Obviously such varied kinetics must result in marked changes in relative distributions with time. Many tissues with high concentrations initially—for example, liver—lose isotope so rapidly that they soon contain less than many tissues of initially lower content. This “redistribution with time” is partly an active redistribution, partly only the result of different retention times. After a few months, a very significant fraction of the body burden of polonium is found in blood cells. Their contribution to the radiation dose, which may be quite significant, is discussed later.

The radiation doses to different individual tissues are not those predicted for the average tissue or from initial distribution. (Stannard and Casarett, 1964, p. 405)

Also:

Our long-term multiple-dose experiment demonstrated how wrong extrapolations from single-dose data may be in predicting tissue concentrations over long periods. First, the equilibrium body burden on a monthly dosage regimen was twice the monthly dose, rather than one and one-half times as predicted from single-dose data. The urinary excretion was slower; the effective half-life (whole body) was 40 days rather than 30 days, and the pattern of tissue contents was always more nearly that at shorter times than at longer times after a single dose. This latter relation might be predicted from the fact that an appreciable fraction of the body burden at any given time is from relatively recently acquired doses.

The relative radiation doses to various critical organs with constant body burden are shown in Table II. The contrast between these and the doses after comparable single administration is clear. The cumulative difference is reduced somewhat, of course, by the fact that a considerable fraction of the radiation dose occurs within a few months after a single injection.

Multiple exposures by inhalation were carried out by Berke and DiPasqua, but the time scale was much shorter (10 days) than in the maintained body burden experiments. In this short time no marked contrast was seen between the accumulation and distribution of polonium in tissues predicted from single doses and the concentrations found after multiple exposures. Delayed excretion was considerably more rapid after multiple exposures, however, and the lung clearance could be described by a single exponential function of time rather than by a compound function. The relative blood concentration rises after either single or multiple exposures to a value well above that of spleen or kidney about 2 months after cessation of exposure. This is reminiscent of the contrasts between oral and intravenous entry routes and may represent a gradual release of ‘solubilized’ or ‘ionic’ polonium from reservoirs in lung and tissues of the reticuloendothelial system and gradual release of ions bound to protein. (Stannard and Casarett, 1964, pp. 406-407)

At Mound Laboratory, a multiple-dose experiment of long duration was also carried out (Davis, Rockhold, and Anthony 1954). It used 120 Sprague-Dawley rats that received about $2 \mu\text{Ci/kg}$ of ^{210}Po intravenously at fourteen-day intervals for ten injections. The body burden was approaching equilibrium in the females, but not in the males, by the 139th day. The “constant” body burden approached was about $6 \mu\text{Ci/kg}$, considerably above the equilibrium body burden of twice the monthly dose described for the Rochester-Wistar rats. This may seem logical because the injections were twice as frequent. However, with an effective half-life of about 30 days, the body burden in the Mound Laboratory experiment should have continued to increase. It is possible that the equilibrium level had actually not been reached, or there is some other difference

between the experiments. However, the Mound Laboratory experiment was not designed so much for comparison of metabolic parameters as for eventual effects. Therefore, the authors do not emphasize possible differences in pharmacokinetics. Except for the difference in possible equilibrium values, a review of the data does not indicate significant conflicts with the Rochester experiment.

The ever-present problem of the extent to which the animal data on metabolism can be applied to humans was attacked by Stannard and Smith (1964). They concluded that the differences in distribution patterns are no greater among species than through variation in route of administration, etc. Excretion patterns did seem to be consistently different, with the rabbit excreting more polonium in urine and the dog consistently less. People seem to resemble the rat more than other species in both relative rate and the proportion in urine versus feces.

At Mound Laboratory (Naimark 1948; Svirbely 1949), the effective half-life in humans was estimated from excretion data on workers as averaging 31.4 days. This is, of course, well within the range of effective half-life in the rat. Using data from accidental inhalation exposures, Naimark (1948) calculated an effective half-life in man of 33 days (range 21.7 to 45.5 days).

D. Effects

It is in the area of effects that the postwar work with polonium added entirely new dimensions to our understanding of the biological effects of polonium, of other alpha-particle emitters, and radionuclides in general. They are described well in the literature, so we will be content with examining the highlights.

1. Long-Term Effects Work at Argonne National Laboratory

At ANL, work with the mouse was carried out to 500 days, as reported by Finkel and Hirsch in an ANL report (1954). Low doses (e.g., $0.004 \mu\text{Ci/g}$), which had seemed innocuous in terms of life-span shortening at 300 days, showed definite effects by 500 days. Only doses of 0.0015 and $0.00046 \mu\text{Ci/g}$ failed to shorten life span. (As so frequently occurs, the survival times were even a little bit longer than the controls at these very low levels.) Also, the body weight changes in the $0.004\text{-}\mu\text{Ci/g}$ group became significantly different from controls after 350 days. Using the plotted survival curve, Finkel and Hirsch calculated that one-half of the 30-day LD_{50} would kill 50% of the mice by 125 days, and one-tenth of the LD_{50} would accomplish this in 485 days.

Of greatest interest is the report of cancer incidence in this experiment at Argonne.^(a) Lymphomas were in high incidence at 0.0015- and $0.0009\text{-}\mu\text{Ci/g}$ doses by 250 days. There was a statistically significant increase in malignant bone tumors even at $0.00046 \mu\text{Ci/g}$.^(b) Indeed, the authors conclude that even their lowest dose was not without deleterious effect in the long term.

(a) Increases in tumor incidence were not described in the war work partly because the times were too short and partly because of the orientation of the investigations.

(b) The appearance of bone tumors is somewhat puzzling for a soft-tissue seeker like polonium. The authors do not comment on the phenomenon. It may be speculated that the tumors arose from deposits in the RE elements of bone marrow. The incidence, while significant, is relatively low (maximum 5.9%) compared to lymphoma (maximum about 48%) and miscellaneous soft-tissue tumors (maximum about 30%). It is much lower than for the bone-seeking elements at equivalent points in the life span. All of these incidences were above the control levels, of course.

2. Effects Work at Mound Laboratory

At Mound Laboratory, Spoerl and Anthony (1956) reported acute and subacute toxicity in the Moyer Monograph. The average twenty-day LD_{50} in the Sprague-Dawley rat after intravenous administration was $43 \mu\text{Ci/kg}$ in males and $36 \mu\text{Ci/kg}$ in females. This compares reasonably well with wartime figures for acute toxicity from Argonne and Rochester. The values were much higher by gavage.

In a group of twelve mongrel dogs, the twenty-day LD_{50} appeared to be about $70 \mu\text{Ci/kg}$ body weight. In cats it was $69 \mu\text{Ci/kg}$, and in rabbits it was in the same region. Thus, the rat seemed to be more sensitive. The authors comment that this proved that the rat was an "excellent choice" for the bulk of the work at Mound Laboratory since it was the most sensitive species.

The Mound Laboratory data for chronic toxicity in the rat extended to about six hundred days. It can be seen from figure 4.5, taken from the Spoerl-Anthony work, that median lethal time was slightly shorter than for the controls at all four of the lower dosage levels, but statistical significance was difficult to work out. The authors remark on an apparently greater sensitivity of the male rat, but this may be a quirk of the data because of the great variability in the female life spans.

Tumors appearing in the Mound Laboratory work were all of soft tissue, and occurrence was independent of polonium dose and was the same as in the controls. Thus, it appeared in this work that polonium was not a carcinogenic element, in sharp contrast to the Argonne and Rochester work. However, the incidence in unexposed Sprague-Dawley rats was quite high, and this may have masked any effects of polonium.

In other respects, the Mound Laboratory histopathology results were, in general, similar to those reported from the war studies elsewhere and to the work going on simultaneously at Rochester. Each quarterly report carried an update of their findings, the chapter by Spoerl and Anthony gives a summary, and a special report by Cowden (1952) was devoted entirely to their single-dose histopathological studies. The work involved single doses from 35 to $0.9 \mu\text{Ci/kg}$ with serial sacrifices up to 375 days postinjection. The most susceptible organs to polonium were kidney, gonads, lymphoid tissue, and "blood" (by which I assume they mean the formed elements of the blood).

The Mound Laboratory also did repeated injection series with doses given each month and, thus, just replacing that lost by decay and excretion. This was in addition to the biweekly injection experiment mentioned in the section on distribution and excretion. This was essentially in parallel, but independent of the maintained body-burden experiment at Rochester. The authors concluded that a maintained body burden of $0.01 \mu\text{Ci/kg}$ failed to shorten life span. The pathological changes at higher levels appeared earlier, were more marked, and involved liver to a much greater degree in the multiple-dose regime. All but the liver changes might be expected if polonium behaved like low-linear-energy-transfer (LET) radiation, and recovery could occur after a dose. (The radiation dose was, of course, higher at early times after a single injection.) But as will be discussed in connection with the Rochester work, it appears that there is little recovery from alpha-particle irradiation. Therefore, these differences in pathology must have another explanation. The authors do not discuss possible mechanisms. The large effect on liver is especially notable. The rest of the pathology findings (Cowden and Zipf 1956) are essentially classic radiation effects.

A unique experiment on reproductive function was carried out by the Mound Laboratory group. Noting the diminution in spermatozoa and long oestrus

FIGURE 4.5. Median lethal times versus dose in Sprague-Dawley rats receiving ^{210}Po intravenously. (Redrawn from Spoerl and Anthony 1956.)

periods in the animals receiving polonium, they tried some mating experiments. The dose was $14 \mu\text{Ci/kg}$, not a small one. The litter sizes were about the same as normal, or larger, but the number of stillborn was markedly increased, especially if both parents had received polonium.

In a paper delivered at the first Atoms for Peace Conference in 1955, summarizing much of the Mound Laboratory work, Anthony et al. (1956) conclude that the minimum effective single dose of polonium is not less than $0.25 \mu\text{Ci/kg}$, perhaps $0.5 \mu\text{Ci/kg}$ in the rat. A body burden of $0.01 \mu\text{Ci/kg}$ maintained throughout life was considered to be without statistically demonstrable effect on any system (not just measured as life-span shortening).

A final contribution from the Mound Laboratory group, "The Effects of Small Amounts of Polonium on Rats," was seen in manuscript form only, sometime shortly after 1964. All of the authors give new addresses, so it is virtually a swan

song. After reviewing their large long-term studies (results already discussed), they caution against ever trying to set exposure levels for radioisotopes, or potentially toxic drugs, from data covering relatively short periods of time (e.g., only long enough to ensure complete elimination of the agent). In these days of emphasis on low-dose, long-term effects determined experimentally to the greatest degree possible, it is hard to realize that such advice was much needed only two decades ago. It is only now being heeded in some other branches of toxicology.

3. Long-Term Effects Work at Rochester

Work at Rochester on the biological effects of ^{210}Po begun during the war years was extended and amplified primarily because polonium gave a rich opportunity to uncover the effects of alpha particles on soft tissue. The impetus during the war to solve practical exposure problems was reduced. Radon, the other possible choice as a relatively pure alpha emitter, was a very poor second because of its relatively short half-life and the interfering daughter products. The solution chemistry and distribution and excretion work were necessary prologues, but only that. A good half of the 442 pages of the Polonium Supplement (Stannard and Casarett 1964) are devoted to effects work.

It all started with George Casarett's Ph.D. thesis, which reported in depth on a long-term serial sacrifice experiment at four intravenous dosages: 1, 5, 10, and $20\ \mu\text{Ci/kg}$ in the rat. It was, I believe, the first Ph.D. thesis at Rochester to require binding in two volumes. It was first issued as a Project Report (G. W. Casarett 1952).

But let us start with the extensions of acute toxicity work. The earlier figures for LD_{50} were essentially confirmed. A separate study of the effect of *Bartonella muris* infection was undertaken (Scott and Stannard 1954) since there was concern that this endemic infection of the hematopoietic system might influence toxicity. The Rochester colony harbored the infection. The Sprague-Dawley colony at Mound Laboratory did not. Scott and Stannard showed that the LD_{50} values for rats from the two laboratories were essentially the same, so this complication could be checked off. (Nevertheless, efforts were made to eliminate it from any long-term study groups.)

Possibly the most interesting addition to knowledge of acute toxicity of polonium was in the paper by Della Rosa and Stannard (1964). They showed that, despite the rather large differences in tissue distribution brought about by using different routes of administration, acute toxicity was essentially identical. Figure 4.6 illustrates the findings.

Table V of the quoted paper gives median survival times for rat, dog, cat, and mouse, which support the conclusion that acute toxicity is more comparable than the differences in tissue distribution would predict. From this came the postulate that acute toxicity, perhaps also subacute, of substances like polonium, with fairly generalized distributions to tissues, and despite real differences in details of the distribution, was proportional to total body burden. It led also to consideration of the role that the polonium in circulating blood could play in producing effects, which might override differences in dose expected from the tissue contents. It also brought into question the validity of the critical organ concept for calculation of maximum permissible exposures (chapter 16).

A large effort was put into measuring life-span shortening. That from a single dose was analyzed by Blair (1964). He applied the same mathematical formulation that he used previously for external radiation and found it worked for

FIGURE 4.6. The mean survival time of Wistar-Rochester rats as a function of polonium dosage. In the case of intravenous injection, the figures on the ordinate refer to injected dose. In the case of all other routes the dosage axis refers to the initial body burden as extrapolated from measurements of actual body burden at time of death in each animal. . . . All experiments are described in the . . . paper except the data from Fink, which are contained in [a] reference. The trend line is the one drawn by Fink to describe the original intravenous studies. (Redrawn from Della Rosa and Stannard 1964. Reprinted with permission of Academic Press, Inc., Orlando, Florida, copyright 1964.)

polonium too. But the fraction of injury defined as irreversible averaged 0.8 for polonium against 0.04 for protracted x rays, an effectiveness ratio of 60. Using already published data in rat and mouse for radium and plutonium, Blair concluded that the life-shortening by polonium, plutonium, and radium stood in the relationship $1 \mu\text{Ci Po} = 0.9 \mu\text{Ci Pu} = 5 \mu\text{Ci Ra}$. The resemblance of these figures to long-term toxicity ratios derived by other means (chapters 7 and 8) is of special interest.

If a large part of the injury brought about by polonium alpha particles is irreversible, then the effects of multiple doses should be quantitatively similar to those from a single dose of the same magnitude. Testing this was one of the chief motivations for the long-term multiple dose experiment. The analysis of Stannard, Blair, and Baxter (1964) confirmed this postulate. Using life-span shortening as the criterion, they found good agreement between the life-shortening

produced by the same total dose attained in a single injection or by multiple injections in the male rat. Also, the shortening was proportional roughly to total dose regardless of regimen. They used several options for expressing dose and mathematical analyses based on the weeks of life-span shortening per microcurie as well as graphical analysis. The female rats showed a tendency for more life-span shortening on the multiple-dose regimen. Also, it was not linear with dose.^(a) No ready explanation could be found for the difference between males and females. However, both sets of data are consistent with the idea that the life-shortening was comparable on the two regimes and that the injury produced was largely irreversible. The highest dose point was somewhat below the line for single-dose data, which might be expected if there were a small fraction of reversible injury. Thus, the fraction 0.8, derived from the single-dose work, may be applicable to the multiple-dose regime. But this requires confirmation. Incidentally, multiple doses of the beta-emitter ⁸⁹Sr were found in work at Argonne to be less effective per unit of dose than single doses, as might be expected from the much lower LET of the beta particle. The relation of this work to other long-term experiments is examined in some detail in the cited publications.

The balance of the Rochester effort concerned histopathology and physiological changes. Only the highlights of the histopathology can be considered here. They are contained in four detailed reports by G. W. Casarett (1964a,b,c,d). These cite earlier publications with even more details. A few points requiring special mention follow.

1. A very clear case was made for the development of arteriolar nephrosclerosis as an overriding mechanism of action. This was accompanied by histopathological signs of hypertension. It was quite dependent on dose, being at a maximum at a dose of 10 μ Ci/kg, almost absent at 1 μ Ci/kg, mild at 5 μ Ci/kg and 20 μ Ci/kg. A dramatic picture of the proliferation of arteriolar endothelium in kidney cortex resulting in sclerosis of an arteriole next to a glomerulus is found in figure 20 of Casarett's paper on the pathology of single doses (G. W. Casarett 1964a).
2. In the absence of generalized arteriosclerosis and attendant hypertension, "the sites and degrees of early and late pathologic effects of polonium corresponded directly with the sites and degrees (concentration and duration) of deposition of the polonium in the body, conditioned by the relative radiation sensitivity of the tissue components" (Stannard and Casarett 1964, p. 415).
3. The factors contributing to death differed to some extent with differences in temporal modes and route of administration.
4. Neoplasms were stimulated in incidence, in shortening of time of onset, and in degree of malignancy. This contrasts with the apparent lack of carcinogenicity in the Mound Laboratory experiments. They were largely sarcomas and carcinomas of soft tissue. The incidence of malignant renal tumors was uniquely high. Leukemia incidence was low, but probably higher than in untreated animals. Bone tumors were not found, in contrast to the Argonne work with the CF1 mouse. Similar increases in tumor incidence, time of occurrence, and malignancy were seen in the long-term multiple-dose experiment, but there were temporal differences.

(a) This is of interest in the light of postulates from the Utah group that protraction of exposure to alpha particles increases effectiveness (Spiess and Mays 1973).

5. The important arteriolar nephrosclerosis, which developed in the single-dose animals, began to develop in the multiple-dose experiment but did not progress even at the dosage level most comparable to a single dose of 10 $\mu\text{Ci/kg}$. Nor did it develop at other dosage levels in the multiple-dose series.
6. No changes attributable to direct effects of polonium were seen in liver on either single- or multiple-dose regimes. The Mound Laboratory work showed extensive liver damage in their multiple-dose series with a body burden of about 6 $\mu\text{Ci/kg}$. This was higher than the highest maintained body burden in the Rochester multiple-dose experiment.
7. After oral administration of an absorbed dose of 25 $\mu\text{Ci/kg}$, there were, of course, effects in the GI tract, and, as might be predicted from the blood and kidney content of polonium, definite changes in kidney. This included nephrosclerosis of the type seen at a single intravenous dose of 10 $\mu\text{Ci/kg}$. It appears that a dose of 25 $\mu\text{Ci/kg}$ absorbed after gavage is equivalent to 10 $\mu\text{Ci/kg}$ given intravenously, and the nephrosclerosis was almost as severe.
8. Changes in testis and ovary would predict definite effects on fertility, but not uncomplicated by other effects that would compromise the reproductive process.
9. Specific changes in lung were not found after intratracheal injection. Three squamous carcinomas of the lung occurred, but it was not possible to prove that these were induced by the polonium. (See chapter 9 for later inhalation studies.)

The final chapter of the postwar research on polonium at Rochester was in the area of functional change.

With microscopic evidence of hypertension, it was logical to make some direct blood pressure measurements. This was done by Sproul, Baxter, and Tuttle (1964) using Long-Evans rats and an indirect noninvasive measurement technique. The experiment was arranged to imitate the condition of the 10- $\mu\text{Ci/kg}$ level in the single-dose Rochester-Wistar rats. There was no doubt about increases in blood pressure taking place as a function of time after injection, beginning at about four months postinjection. They were statistically significant ($P = < 0.01$) at all times after four months, and the increase was enough to be biologically significant as well.

Because of experience with cataract development with external radiation sources, especially those of high LET, these authors also examined the animals with a slit-lamp microscope. Increased opacity began in the injected animals at about six months and reached close to 100% by one year. Control animals developed far fewer cataracts, and these at later times.

Using changes in specific gravity of urine as a test, Sproul and coworkers (1964) showed progressive decreases in kidney efficiency. There was a progressive decrease in specific gravity of urine indicating progressive failure of the kidney to concentrate the glomerular filtrate.

The radiation doses associated with these changes were calculated. They ranged from nearly 5,000 rad to spleen at 350 days to 137 rad to the whole body at 100 days. Thus, we are dealing with phenomena at quite substantial doses.

Tuttle and Baxter (1964) measured reticuloendothelial (RE) function in rats receiving about 7.4 μCi (i.e., an estimated thirty-day LD_{50}) by the uptake of ^{32}P -labeled chromic phosphate. The changes were not large nor considered of much biological significance. These facts fall in line with other indications of

either considerable radioresistance or marked ability to repair damage in the elements of the RES. If one muses that the function of such cells is to rid the body of "foreign invaders," it seems fitting that they should be resistant to toxic agents of various kinds. (They are not always resistant, as we shall see in the USSR work on thorium.)

4. Other Effects Work in the United States

Investigation of the biological effects of ^{210}Po in the United States was, of course, not confined to the laboratories mentioned above. This was particularly true of work associated with possible effects of naturally occurring polonium, as will be seen in section V.

An important addition to the stock of knowledge on effects in the reproductive system came from L. D. Samuels at the Harvard School of Public Health (Samuels 1966). Using the mouse and polonium obtained from England, he gave doses from 10 to 2,000 pCi/g and measured the survival of resting primary spermatocytes. All but the lowest level produced very significant depletion, with gradual recovery. At the two higher doses (600 and 2,000 pCi/g), recovery was slow and incomplete. As might be expected from what we know of alpha-particle effects and the fact that the polonium remains in the testes for a considerable time, the effects were greater and less reversible than from doses of x rays. The local doses were calculated, and the minimally effective one was about 3 rem.

Interest in polonium continued at the Harvard Laboratory in Little's work that concerned primarily effects in the lung. This will be considered in chapter 9.^(a)

E. Work Abroad on Distribution, Excretion, and Effects of Polonium

1. USSR Work

The rather considerable effort in the USSR has already been cited (Moroz and Parfenov 1972a). A shorter but still quite complete version is found in a later review (Moroz and Parfenov 1972b). Because of space limitations and the mission of this book, only very brief consideration can be given to the results.

On the whole, their findings dovetail very nicely with the work done in U.S. laboratories. In many chapters of Moroz and Parfenov (1972a), the results from Rochester are considered along with their own, and the open literature work of Anthony is quoted. The bibliography contains 417 references, a plurality of them work in the USSR. This gives a notion of the extent of their interest in polonium.

There is much more work with the dog than in U.S., British, or German studies. The acute LD_{50} for twenty days is $0.05 \mu\text{Ci/g}$ ($50 \mu\text{Ci/kg}$) and for thirty days $0.03 \mu\text{Ci/g}$ ($30 \mu\text{Ci/kg}$). These indicate sensitivity to acute damage in the dog comparable to that of other species. They arrive at a minimally effective dose of about $0.01 \mu\text{Ci/kg}$ comparable to the "no effect level" arrived at by Anthony et al. They quote work showing that the reduction of life span is linearly related to dose.

(a) Work done on possible therapeutic removal of polonium will be dealt with in the chapter on therapy. Aspects such as its use for detecting deposits of ^{210}Pb have been considered along with the uranium mining problems in chapter 3.

Clinical observations in all species are reported in depth. There is much more emphasis on changes in the nervous system, the endocrines, immune system, and the general stress syndrome than in the postwar American work. While the wartime American work paid more attention to general pathophysiological effects than did postwar research, the USSR studies went further than any. There is a full chapter on the reaction of the sympathoadrenal system, on changes in function of the adrenal cortex, on electrolyte metabolism, and much detail on electrocardiographic changes, the coronary circulation, and the "reactivity" of the cardiovascular system. It is not easy to separate out which of these many functional changes were specific to polonium and which to the generalized radiation sickness induced by the fairly high doses of polonium administered. Perhaps it is not important to make such a distinction anyway.

Decreases in blood pressure were noted in rabbits soon after polonium administration. The observation periods were much too short to allow development of the hypertension seen in the rat at Rochester associated with nephrosclerosis. The Moroz monograph devotes some space to long-term effects, but the cited works are mostly American. The USSR work describes increased incidences of lymphomas, lung cancer, and neoplasms of the mammary and sex glands in mice and rats. Kidney tumors were described in rats receiving doses of 5 and 2.5 $\mu\text{Ci/kg}$. The unique kidney lesion described by G. W. Casarett (1964a) was not remarked upon. This is not surprising since its incidence is limited to a narrow range of doses.

Clearly, the quite extensive USSR studies with polonium possess many features not so fully investigated in American or British work. The primary findings are, in general, similar, as they had to be. There are occasional differences in fact or interpretation (e.g., effects in brain). But when these do occur they are pointed out, and they are not major.

2. Other Work Abroad

Despite much attention to alpha emitters in the postwar years in England, France, and Germany, relatively little work was done on polonium *per se*, except for its appearance in the environment and various aspects of radon daughter investigations. Even in France, with the impetus given by the Curies and Lacassagne, biomedical interest went to other elements emitting alpha particles.

Some work was done on chemical binding in tissues at the Institute of Cancer Research in Sutton, Surrey, U.K., with collaboration from Italian investigators at Pavia (Lanzola, Allegrini, and Taylor 1973). A symposium on all aspects of polonium metabolism and effects was held also at Sutton, Surrey in 1970, with an internationally derived set of participants. The proceedings of this excellent meeting were never published, and we have only a copy of the program and abstracts for a permanent record (U.K. Polonium Symposium 1970).

On the whole, the bulk of the work of the type described thus far in this chapter was done in France, the United States, and the Soviet Union.

V. Polonium in the Environment, Especially in Tobacco

A. Introduction

It would be expected that measurable amounts of polonium would exist in the environment as a result of decay of uranium and radium in the earth's crust,

and from radon and its daughter products in the atmosphere or water. Furthermore, it would have many opportunities to enter the food chain and be incorporated in the bodies of animals and man. The accumulation of ^{210}Pb in bone by development in vivo from deposited radium or radon daughter products can lead to production of polonium in situ, and excretion in urine, which could conceivably be used as a measure of radon exposure (Sultzer and Hursh 1954).

A substantial amount of research has been done both to measure the amounts present in various natural environments and to gauge increments due to the activities of man. Unlike the experimental research we have been discussing, this work consists primarily of measuring how much is present, in what form, the influence of various factors on the form and amount present, and then speculating on the possible biological significance of the amounts found.

While we are saving much of our discussion of environmental research for the discussion of fallout, work around nuclear installations, and the development of the field of "radioecology," a brief review is pertinent here while we are engaged with polonium and its effects. No particular laboratory can be singled out for separate presentation because the work on naturally occurring polonium was usually part of a broad spectrum of such activities in various institutions. The most complete discussions appear in the USSR Monograph (Moroz and Parfenov 1972a), a report by the National Council on Radiation Protection and Measurements on natural background radiation (NCRP 1975),^(a) and several reports from the Scripps Institution of Oceanography of the University of California at La Jolla (Folsom, Wong, and Hodge 1972).

B. Natural Occurrence of Polonium

Concentrations of ^{210}Po in air, rain water, plants, marine plankton, drinking water, food products, and in animals and man are reported in detail by Moroz and Parfenov (1972a,b). They cite, in addition to voluminous USSR sources, work by Holtzman at Argonne National Laboratory, Blanchard from the U.S. Public Health Service, Hill in the United Kingdom, Globel and Rajewsky in Germany, and others. The "natural intake" may be direct or indirect by production of polonium in vivo from precursors.

The largest natural terrestrial sources are inhalation of aerosols of ^{210}Pb - ^{210}Po , plus ingestion of polonium in drinking water and food. Ingestion of some sea-food products gives higher than average intake because of the accumulation of polonium in the marine trophic sequence (Folsom, Wong, and Hodge 1972) to be discussed presently.

The natural burdens in the tissues of man are in the range from a few picocuries per kilogram to a fraction of a picocurie. Hill (1965) reports, for example, 7 to 10 pCi/kg in normal human liver tissues, and this is among the highest concentrations found. The metabolic balances of ^{210}Pb and ^{210}Po were measured in twelve men maintained on a metabolic ward by Holtzman et al. (1974) at Argonne National Laboratory. Mean levels of dietary intake were about 1.6 pCi/day over a period of five months. Excretion exceeded dietary intake by a small amount, being 0.27 pCi/day in urine and 1.9 pCi/day in feces. Atmospheric concentrations were not sufficient to make up the balance, but cigarette

(a) Extended and confirmed by a recent NCRP report seen in draft form (NCRP 1986).

smoke could (see later section). Thus, none of these levels of natural occurrence in man is high in an absolute sense. Overt biological effects would not be incontrovertibly expected from such concentrations in themselves.

An interesting exception occurs in the far North. In Lapland and Alaska, the intake by man can be well above average because of the lichen-reindeer-man food chain. Lichens accumulate large amounts of many radioisotopes simply by virtue of their long life (estimated at hundreds, even thousands of years), and polonium appears in them in concentrations many times those seen in ordinary grass and other plants. Since reindeer and caribou feed largely on lichens part of the year, any residents of the far North consuming much reindeer or caribou meat have both higher intakes and higher body burdens of polonium. The accumulation in lichens is tenfold that of the usual plants of temperate latitudes. Hill (1965) estimates that the concentration of ^{210}Po in reindeer skeleton is twenty times the level in cattle in temperate latitudes. (Remember that radiolead is in skeleton, and the polonium can be generated in situ from it.) That in reindeer muscle is higher by a factor of two. Kauranen and Miettinen (1967) estimate the concentrations in tissues of reindeer at ten times those in elk, which do not feed on lichens. Thus, sometimes the factor by which polonium concentrations in the bodies of human inhabitants of the far North who eat reindeer and caribou meat exceeds that of those from other areas by as much as one hundred (work of Mayneord and Hill; Hill; Holtzman; the Miettinen group and others cited by Moroz and Parfenov 1972a).

The NCRP report (1975) presents estimates of dosages in man from a large number of internally deposited nuclides acquired naturally. It is of interest that the ^{210}Po dose contribution (in millirem) to gonads, osteocytes, and Haversian canals from cortical bone deposits of the precursor ^{210}Pb are easily well ahead of several radium and uranium isotopes and ahead of both ^{222}Ra and ^{226}Ra . Likewise, the calculated "effective MeV" for ^{226}Ra , ^{228}Ra , and the ^{210}Pb series is always maximal for the polonium isotopes. The calculated doses from naturally occurring deposits are of the order of 60 mrem/yr maximum.^(a)

Naturally, all these figures for terrestrial amounts of polonium are subject to geographical variations, especially in consideration of some of the areas of high background radiation. Also, differences occur as a function of factors causing variations within a given environment.

In the marine environment, the situation is quite different. The group at the Soledad Marine Radioactivity Laboratory of the Scripps Institution of Oceanography, La Jolla, California, became engaged with studies of the accumulation of radionuclides from fallout in the oceans of the world and in representative organisms. They placed special emphasis on the Pacific area.

As a corollary, they, and other oceanographic groups, investigated the concentrations of naturally occurring elements. The Scripps researchers became convinced that the alpha emitters had been neglected and made extensive studies of ^{210}Po , in part as a surrogate for plutonium. They were well rewarded for their efforts.

(a) The draft NCRP report cited in the footnote on page 230 calculates annual dose equivalents from ^{210}Pb - ^{210}Po contained in the body as 14 mrem to soft tissue, 60 mrem to bone surfaces, and 14 mrem to bone marrow. Potassium-40 is calculated as contributing 19 mrem/yr to soft tissue, 15 mrem/yr to bone surfaces and to bone marrow. Doses from naturally occurring ^{222}Rn are given as 11 mrem/yr to each tissue named.

Quite high concentrations of polonium were found in a variety of marine organisms, both ones living near the continents where the precursors of polonium exist and in organisms collected from the open ocean. In the albacore tuna, a digestive organ (not canned for human consumption), the pyloric caecal mass, went as high as 79,000 pCi/kg wet weight. This is over two million times the usual concentration in surface sea water. The liver for the common dolphin ran about 4,000 to 11,000 pCi/kg, the lantern fish viscera from 17,000 to 26,000 pCi/kg, and many mollusks showed concentrations in the soft tissues in the same range, although others were much lower. Folsom and coworkers calculated "concentration factors" (the concentration in the organism or tissue of the organism compared to that in surface sea water), a subject we will see more of in chapters 11 through 13, for seven species. The factors are from high to very high. In terms of calculated radiation dose, the authors estimated the maximum (caecal tissues of the albacore tuna) at about 8 rad/yr. If we use a Quality Factor of 10, or the currently accepted 20, the resulting dose is 80 or 160 rem, both of which are well above the current maximum allowable exposures even for occupational situations and far above the permitted population exposure level. Fortunately, the viscera are seldom eaten by man.

A lesson in the need for care in evaluating tissue doses from alpha emitters came from work with the giant kelp (a brown alga). This plant grows luxuriantly just beyond the surf line near San Diego, La Jolla, and similar areas. It is harvested to make agar. Wong, Hodge, and Folsom (1972) found very high concentrations of polonium in this plant. But most of it was on the outermost thin layer of the antlers and bladder tissues. The thickness of the layers is such that only a small fraction of the alpha dose would reach the inner tissues. Much depends on the importance to biological function of the outermost tissue layers. Plutonium was also measured in this work. It showed the same tendency to concentrate on the outer layer but to a much lesser degree. Also, there was much less plutonium present in all tissues.

The high concentrations in areas such as the pyloric caecal mass of pelagic fish may have been partly in the contents and not in the walls of the organ. There seems little doubt that the mechanisms of polonium accumulation are entirely different in the case of these fish than in the giant kelp.

A general survey of midwater fish of the eastern Pacific was carried out by the Scripps group (Hoffman, Hodge, and Folsom 1974) using specimens collected by the Naval Underwater Research and Development Center, San Diego. Most of the polonium was found in the digestive tract, indicating it entered via the food. It seems likely that the concentration process is occurring all along the trophic ladder. Samples of bottom-living fish, which might be near radium deposits on or just below the sea floor, were expected to show high concentrations of polonium. They were moderately high but not enough to pinpoint bottom radium as the source of marine polonium. Furthermore, much of the polonium seemed to be unsupported by ^{210}Pb . We must conclude that the high concentrations in marine organisms result from a catenary series of concentrating steps. But exact details need further examination. The factor between the liver of man and albacore liver is about one thousand, not so large, naturally, as the comparison to sea water, but still a phenomenon to be reckoned with.

C. Polonium in Tobacco

The marked increase in incidence of lung cancer and the role of smoking in its causation has naturally turned attention to the identification of the carcinogenic

agents in tobacco. As evidence developed in laboratory research (chapter 9) that alpha emitters were potent carcinogens to the lung when inhaled as aerosols of plutonium or of polonium, and the dreary saga of the uranium miners unfolded (chapter 3), attention turned to a possible role of naturally occurring polonium in the production of lung cancer in smokers.

In the United States, it was probably Radford, then researchers at the Johns Hopkins University School of Public Health, who diverted attention from the tars in tobacco to its content of radioisotopes. Radford and Hunt (1964) calculated the dose to bronchial epithelium from ^{210}Po inhaled on particles in cigarette smoke. The minimum dose estimate was 36 rem as a result of smoking two packs of cigarettes per day for twenty-five years. This was recalculated by Skrabale and colleagues (1964) using a different mathematical model (that of the International Commission on Radiological Protection [ICRP]) and a much lower figure appeared likely. There was further discussion of the need for better models by Radford and coworkers in the same issue of *Science* (Radford, Hunt, and Little 1964). Biases began to develop among environmentalists and radiation biologists. Actually, Radford was not inclined to push polonium as the causative factor, but he emphasized that "if polonium in smoke is found not to be involved in bronchial carcinogenesis, this will greatly strengthen the view that exposure to chronic low doses of radiation is not hazardous. On the other hand, proof that chronic radiation exposure is involved in production of cancer would have obvious significance." In 1966, Rajewsky and Stahlhofen considered the doses far too low to be causative agents. And so it went. To a degree, this pushed the story of polonium in tobacco into the raging controversy on the effects of low levels of radiation and made it front-page news.

Further work was done in several laboratories. It became clear that the polonium content of tobacco could vary considerably in different types of tobacco and in different locations. It also seemed that the polonium content was largely foliar, which indicated deposition from the air rather than uptake from the soil. Lead-210/polonium-210 ratios were used to determine how long the insoluble particles from cigarette smoke remained on bronchial epithelium (Radford and Martell 1976), a much needed parameter. The polonium content of many plants was measured. There were not large differences in initial content. But Martell (1974) found that ^{210}Pb activity of tobacco was transformed into insoluble particles by the curing process. Also, the small trichomes on the surface of the tobacco leaf entered the smoke stream and were deposited in the lungs. Here they produced high local alpha irradiation sources by the ingrowth of ^{210}Po . Indeed, the same trichomes are covered with a sticky hydrophobic substance that makes foliar deposits of ^{210}Pb or ^{210}Po stick on the leaf, whereas they might wash off from other plant leaves.

The monograph by Moroz and Parfénov (1972a) considers the intake of ^{210}Po during tobacco smoking and remarks that the urinary output of polonium is sometimes higher in smokers. However, they quote the work of Little et al. (1964), which shows no significant differences in tissue contents of polonium in smokers versus nonsmokers. But Blanchard (1967) later measured average concentrations of polonium in several tissues and found those in smokers to be slightly higher than in nonsmokers. Only the difference in concentrations in lung was statistically significant. Hill (1965) placed the difference in lung tissue at two- to threefold.

Some of the most recent work on polonium and other alpha emitters in the lung from cigarette smoking comes from New York University. It started with

Bernie Cohen's Ph.D. thesis (1979) and was taken up by N. H. Harley et al. (1979) as principal investigators, Kuschner and M. E. Wrenn as coinvestigators, and B. S. Cohen as "staff." Cohen et al. looked at the distribution of ^{210}Pb in the human lung (1978, 1979). The most recent findings are presented in the 1979 annual report. They measured ^{210}Po in cigarette smoke tar, then let it stand for decay of the polonium. The measured values for alpha activity were about 10 fCi/cigarette.

They then turned to analyses of human lung tissue using a cellulose nitrate etch film to detect the extraordinarily low values found in the bronchial tree. While there were some variations with age and some areas of higher concentration (by a factor of about one thousand), the usual concentration was a fraction of a femtocurie per square meter or about 20 fCi in the entire tracheobronchial tree. Translated to radiation dose, the average was about 1 mrad/yr, but with one or two "hot spots" at about 1 rad/yr. Significance depends much upon the real importance of such "hot spots"—a subject we will take up in chapter 9.

Since it is in the bronchi that the tumors arise, the research and the polemic had to focus on the polonium concentrations in bronchial epithelium. The results are discouragingly disparate. Not only do different investigators (by and large the ones we have already cited) differ, but their models for dose calculation are even more disparate. Moroz and Parfenov (1972a) present a full summary of the work until 1971. Their final statement sums it up well: "Thus, smoking of two packs of cigarettes a day leads to supplementary irradiation of the lungs of the smoker, equal to 0.1-100-fold absorbed dose rate in comparison with the natural background" (Moroz and Parfenov 1972a, p. 27).

An especially frustrating aspect of this wide range of possible doses is the fact that the highest approach potential biological significance, while the lowest are far too low to account for the statistics on lung-cancer incidence in smokers. Probably further research of the same nature will do little to solve the problem. Equal efforts on the basic mechanisms would be preferable, especially when we remember the growing opinion that many cancers, if not most, have multiple causation. That polonium helps to trigger a cancer already "set up" by chemical carcinogens, or vice-versa, or that there is no such effect at all, is a more interesting line of attack than more measurements of concentration. Probably for this reason, and perhaps frustration, the amount of work on polonium in tobacco and in lungs and tissues of smokers has fallen off considerably in recent years.^(a)

Part B. Thorium

I. Introduction

We are interested in thorium as a generic term for a number of different isotopes and many compounds. In the days before electric lights, fine illumination could be obtained from a gas or kerosene flame making incandescent a mantle

(a) The subject has been revived in the draft NCRP report (1986) cited earlier (footnotes, pp. 230, 231). As part of a consideration of radiation exposure to the U.S. population, it was evident that the annual effective dose equivalent to smokers far exceeded that to non-smokers, i.e., 1,660 mrem versus 365 mrem. Further, the report ascribed most of the dose to ^{210}Po - ^{210}Pb . Whether or not this is sufficient to cause lung cancer by itself is still problematical.

devised by Welsbach. This mantle was prepared from thoria but had other components also. Although its use peaked around the turn of the century, there is still much demand for such mantles from campers, the Armed Forces, etc. Thorium ores were mined and handled in quantities far larger than uranium at the time. Thorium is also used in alloys and in the making of refractories.

A nuclear fuel cycle based on the conversion of thorium to the fissionable ^{233}U has much potential and has recently stimulated a flurry of activity in the biomedical realm. Such a cycle might be brought into play if uranium reserves are depleted, because there is considerably more thorium than uranium in the earth's crust. Good summaries of its properties are given by Wrenn (1977), by Stover (1981), and in International Symposia (1963, 1965, 1968).

Biomedical research with thorium was relatively low-key during the years of World War II. It was neither a new substance nor one expected to be used in large quantities. There were no crash programs, and no single laboratory devoted more than a fraction of its efforts and resources to the subject. It was, however, an important complication in the luminous dial painter cases, as we saw in chapter 1.

It received more attention in the postwar years. This was partly to help understand better some of the luminous dial painter problems, partly through the ^{224}Ra story we reviewed in chapter 1. But it was largely through the realization that a new and large population of exposed humans was in our midst. This was the population, or rather several populations, of thousands of patients who had received the radiopaque medium "Thorotrast" in diagnostic radiology.

After a review of natural thorium and its effects and the distribution and excretion of thorium isotopes in animals and man, we will pursue a brief analysis of the Thorotrast problem and of the effects of short half-life isotopes of thorium.

II. The Setting and the Problems

When we depict the three naturally occurring series of radioisotopes as we did in the preface to these four chapters, we seldom pause to pay tribute to those who devoted whole careers to unraveling the natural decay series. Brucer (1981) describes a part of the process, including the sometimes acrimonious arguments among the radiochemists. (Hahn and Boltwood, for example, could agree only on the quality of Munich beer, which they longed for while working temporarily in the New World with Rutherford at Montreal [Brucer]). The thorium series was an especially complex one to work out, partly because the activity could range from very low and almost invariant with time to moderately high and with marked changes with time, all dependent on previous treatment of the source material.

In table 4.2, the elements of the thorium series are shown. Table 4.3 shows the uranium series. The contrast in properties of the two series is immediately apparent. All daughter products of ^{232}Th have relatively short half-lives, and the parent has a very long half-life. Thus, in contrast to the situation in the uranium series, rapid changes in activity will occur with time if work is begun with thorium separated from the daughters. In the extraction of thorium from ores or from a mixture in secular equilibrium, the ^{232}Th and ^{228}Th stay together and are separated from the radium, actinium, polonium, thoron, bismuth, thallium, and lead isotopes. But these immediately begin to reappear with a time course of gross radioactivity like that shown in figure 4.7.

TABLE 4.2. The Thorium Series

Element	Symbol	Half-life	Energy (MeV)			Percent γ Occurrence
			α	β	γ	
90 thorium	^{232}Th	1.40×10^{10} y	4.00	—	0.06	23
88 radium	^{228}Ra	6.7 y	—	0.054	—	—

FIGURE 4.7. Radioactive “decay” of ^{232}Th plus ^{228}Th showing changes in gross activity with time. (Redrawn from F. L. Cuthbert 1958, *Thorium Production Technology*, p. 246. Reprinted with permission of Addison-Wesley Publishing Co., Inc., Menlo Park, California, copyright 1958.)

In addition, thorium isotopes occur in the other naturally occurring radioactive series. Two of them, ^{234}Th and ^{230}Th , occur in the uranium series; two others, ^{231}Th and ^{227}Th , occur in uranium minerals as members of the ^{235}U decay chain (the actinium series). Thus, if a source such as monazite sand is used, the build-up of daughter activity can be exceedingly complex, as shown in figure 4.8.

Biological studies with such a mishmash of activities coming and going are correspondingly complex and sometimes confusing. On the one hand, “natural thorium” seemed to be almost inert toxicologically. Yet, on the other hand, the maximum permissible body burdens and maximum permissible concentrations of isotopes like ^{228}Th , ^{230}Th , ^{232}Th , and the radioactivity of Th-nat are in the same range as ^{239}Pu , i.e., among the lowest on the books (ICRP 1959; NCRP 1959). In the new ICRP compilations, some of the thorium isotopes have derived air concentrations even below those for ^{239}Pu (ICRP 1979). Are both sets of facts

FIGURE 4.8. Daughter activity build-up from ^{234}Th , ^{231}Th , ^{230}Th , and ^{227}Th present in 1 mc of thorium obtained from Indian monazite. Broken lines are continuation of curves on scale 10^4 to 10^5 (shown at top of graph). (Redrawn from F. L. Cuthbert 1958, *Thorium Production Technology*, p. 246. correct, or has there been a mistake somewhere? The balance of this chapter will address this and other dilemmas posed over the years by the biomedical research with thorium and its wandering daughters.

III. Natural Thorium

A. Is There Such a Thing?

Hursh (1974) addresses this question in detail. In the strict sense and in contrast to natural uranium, there is really no specific entity with more or less constant and predictable isotopic composition present in thorium ores that we can call "natural thorium." Table 4.4, taken from the Hursh paper, shows the "natural" thorium isotopes, their specific activities, and the series in which they belong.

Thorium ores contain varying amounts of U_3O_8 , which can contribute varying amounts of ^{234}Th and ^{230}Th , and also ^{235}U , the precursor of ^{231}Th and ^{227}Th . These several components could hardly be expected to be in consistent ratio in ores

of different origins. They obviously should vary in activity with time after preparation, and there is no "natural thorium" analogous to "natural uranium."

TABLE 4.4. Thorium Isotopes of the Natural Radioactive Series

Nuclide	Half-life	Specific Activity (d/m/g)	Related Natural Series
^{228}Th	1.910 yr	1.82×10^{15}	thorium
^{232}Th	1.41×10^{10} yr	2.43×10^5	
^{230}Th	8.00×10^4 yr	4.32×10^{10}	
^{234}Th	24.10 day	5.14×10^{16}	uranium
^{227}Th	18.2 day	6.86×10^{16}	actinium
^{231}Th	25.52 hr	1.20×10^{18}

B. Chemical Toxicology of Long-Lived Thorium

Long before the realization that "natural" thorium was not an entity of constant composition, toxicological work was done with the thorium mixtures and compounds available. The work goes back as far as 1907 and is in the literature of pharmacology and toxicology. It appeared to be a substance of very low toxicity acutely. It had the general properties of the rare earths, which meant being relatively insoluble except for a few compounds, and it was prone to deposit in the tissues and organs of the RES, i.e., liver, spleen, bone marrow, lymphatics.

During the years of most active work on uranium in the MED, a few thrusts were made to explore similarities and differences between uranium and thorium. Much of this work with "natural" thorium was done at Rochester and was reported in monthly reports. After the war and when the potentials for a thorium-based nuclear cycle drew more attention, the Rochester group looked more seriously at the chemical toxicity of natural thorium (Downs et al. 1959; Hodge and Thomas 1959; Hodge, Maynard, and Leach 1960; and others).

The earlier work (Downs et al.) explored several routes of entry and looked at weight gain, hematology, histopathology, and lethality. Maximum times ranged up to fifty to one hundred days. In a dog experiment (Hodge and Thomas 1959), a few animals were kept as long as seven years following inhalation exposure. (This experiment paralleled the long-term uranium experiment described in chapter 2 but was much smaller.)

There was virtually no specific chemical toxicity of thorium comparable to the nephrotoxic action seen with natural uranium. And despite large calculated radiation doses to the lung of dogs over a two- to seven-year period, essentially no histological evidence of radiation damage could be found. The authors muse on several possible explanations. The most likely one in their opinion is the large amount of self-absorption of the short-track alpha particles and the fact

that the deposits were very uneven and acted like point sources, i.e., large volumes of lung were not irradiated.

Since no quantitative approach was possible, the potential explanations must be considered as possible but not proven. With or without a plausible explanation, these findings were hardly indicative of an element with toxicity comparable to plutonium. Yet, the maximum permissible concentrations put it in that category: a first-class dilemma.

The same dilemma is seen also in the surveys of thorium workers. Albert et al. (1955) looked carefully at the industrial hygiene practices and the medical status of a group of eighty-four employees in a plant extracting thorium and rare earths from monazite ore and manufacturing gas mantles over a thirty-year period. Calculated radiation doses were considerably in excess of current maximum permissible exposures. But again there was no evidence of overt disease attributable to the exposure.

This, plus the animal data, led to the addition of footnotes to the permissible thorium concentrations in both the ICRP and NCRP 1959 reports. These were appended to the $(MPC)_a$ values for ^{232}Th and Th-nat as follows:

Provisional values for Th^{232} and Th-nat. Although calculations and animal experiments suggest that Th-nat, if injected intravenously, is perhaps as hazardous as Pu and indicate the values listed above, experience to date has suggested that in industrial circumstances the hazard of Th-nat is not much greater than that of U-nat. Therefore, pending further investigation the values $(MPC)_a = 3 \times 10^{-11} \mu\text{C}/\text{cm}^3$ for the 40-hour week and $(MPC)_a = 10^{-11} \mu\text{C}/\text{cm}^3$ for continuous occupational exposure (168 hr/wk) are recommended as provisional levels, permissible for exposure to inhaled Th-nat or Th^{232} . However, the values given in Table I are listed to indicate the possibility that further evidence may require lower values and to urge especially that exposure levels for these radionuclides be kept as low as is operationally possible. It may be possible to show that similar considerations apply to other inhaled long-lived thorium isotopes under conditions in which the physical characteristics of the airborne particulates are much the same as in the case of Th-nat, and where there is a large amount of airborne material serving as an effective carrier for the thorium. (ICRP 1959)

and

Provisional values for Th^{232} and Th-nat. Although calculations and animal experiments suggest that Th-nat is perhaps as hazardous as Pu and indicate the values listed above, industrial experience to date has suggested that the hazard of Th-nat is not much greater than that of U-nat. The NCRP has recognized that a certain period of time may be required for adjustment of operations to comply with new recommendations. Therefore, pending further investigation the values $(MPC)_a = 3 \times 10^{-11} \mu\text{C}/\text{cc}$ for the 40-hour week and $(MPC)_a = 10^{-11} \mu\text{C}/\text{cc}$ for continuous occupational exposure (168 hr/wk) are recommended as permissible levels. These values are essentially those that have been generally used in this country (*Federal Register* 1957). However, the values given in Table I are listed to indicate the possibility that further evidence may require lower values and to urge especially that exposure levels of Th-nat be kept as low as is operationally possible. The exception indicated here applies only to the $(MPC)_a$ values for Th-nat and Th^{232} . (NCRP 1959)

Note that the NCRP version is aimed at U.S. practices specifically.

Additional information on the nature of thorium hazards in industry is given in Albert's book (1966) and also in the Russian literature (Tarasenko 1963), but the basic information on the workers did not change the picture much except that more was said about potential hazards.

The need for a caveat in the form of a footnote to the international and national recommendations became the *raison d'être* for a conference on thorium toxicity held in Rochester, New York, January 19-20, 1960. Here the many facets of the biomedical problems with thorium were brought together, and the notion that thorium could be shelved as a toxicologically inert substance was thoroughly dispelled. The several papers given there foreshadowed most of the later toxicological work.^(a)

However, before we can go on to examine the distribution and excretion work and effects, we should pause to consider a wartime sidelight, even though it is not strictly research on the toxicology of internal emitters.

C. A World-War-II False Alarm

In chapter 6 on the fission products, we will review the concerns developed in the Allied High Command during the war in Europe that the Germans were indeed proceeding on a nuclear energy project and might even beat the Allies to producing a nuclear weapon. In Goudsmit's book, *Alsos*,^(b) which is the story of intelligence efforts to learn how much the Germans were really doing, there is a chapter involving thorium. On the liberation of Paris, it was found that a French company, under German supervision, dealing in rare chemicals had a monopoly on thorium and had moved the entire supply of thorium back to Germany. Did the Germans have work going on the thorium cycle? The mystery was further deepened when it was calculated that only a small fraction of that supply would have been needed to meet ordinary industrial needs for the next twenty years! The agents followed every lead and found the principals who were behind the movement of thorium from France to Germany. It consistently dead-ended, however, when they tried to tie it to nuclear energy matters. In fact, the people seemed to be genuinely and totally unaware of what information was being sought. And well they should have been, for it turned out that the huge chemical company concerned (the Auer Company) was planning for the postwar years and realized that the "big money" would be in cosmetics. They had a patent on *thoriated toothpaste* which they expected might compete with Bob Hope and the toothpaste he advertised with "Irium." The world's largest single stored supply of thorium ore appeared to be destined for toothpaste.^(c)

IV. Distribution and Excretion of Thorium Isotopes

A. Animal Studies

Only a fair amount of work has been done with thorium in forms where its distribution and excretion were probably governed by the fact that it was thorium rather than a colloid. There has been much more work on the colloidal

(a) In 1976, AEC's successor agency, ERDA (Energy Research and Development Administration), announced follow-up medical studies to be undertaken by ANL's Center for Human Radiobiology on employees of the Lindsay Light and Chemical Company plant now owned by Kerr-McGee Corporation.

(b) *Alsos*, Samuel A. Goudsmit, Professor of Physics, Northwestern University, Henry Schuman Inc. New York (1947).

(c) Later investigations confirmed that this was indeed all there was to it.

oxide in the form of Thorotrast, or long-lived isotopes in other forms where the behavior is strictly governed by the fact that it is in colloidal form. In some of the work, both situations prevail as a function of the amount of carrier present. This section will address this very basic problem.

While Hevesy looked briefly at the behavior of thorium, the earliest systematic work at truly tracer levels was done at U.C. Berkeley by the Hamilton group (Lanz et al. 1946; Hamilton 1947). This was under the aegis of the Metallurgical Laboratory, which we will see much more of in chapters 6 and 7. The routes were intramuscular or oral, the animals rats, and the injection about 10^{-6} mg of ^{234}Th chloride per kilogram. This experiment involved little or no complication by ingrowing daughter products since ^{234}Th decays with a twenty-four-day half-life via a short-lived beta-emitter, ^{234}Pa , to the very long-lived ^{234}U . It appeared that about 50% of the ^{234}Th deposited in skeleton. This was when the figures were put as percent (adjusted) dose per organ. Thomas (1961) recalculated the figures as fractions of the recovered dose. Since the injections were intramuscular, a large amount of the thorium remained at the injection site and was slowly released to the circulation, where, as Thomas put it, "...it follows what its chemistry demands." On this new basis, bone was still the organ with highest concentration, but it began at only 3% of the recovered dose and gradually rose to 12.2% at sixty-four days. The excretion pattern with time likewise changed qualitatively when expressed on the basis of recovered dose.

But regardless of details of the calculation, the important fact emerges that at tracer levels, and with a slow trickle into blood from the injection site, the organ of principal disposition was clearly bone, not RES tissues. This behavior looks more as an analogue of plutonium should look.

Scott, Neuman, and Bonner (1952) at Rochester gave thorium sulfate to a variety of rodents by several routes of administration. The total thorium concentration was 2.5 mg/kg, and the solution was a mixture of ^{234}Th (UX_1) and "inert" carrier, ^{232}Th . Despite an original plan to do a carrier-free experiment, this one involved carrier and illustrated the marked differences carrier could make. At the higher concentrations, the "soluble" thorium sulfate acted as a quite insoluble salt. It remained at the site of injection, was not absorbed from the gastrointestinal tract, and, after intravenous injection, went largely to liver and spleen.

Boone et al. (1958) at Los Alamos gave ^{230}Th (ionium) plus carrier ^{232}Th to rats as the citrate complex. The amounts given were 8 to 54 mg/kg, much more than in the two experiments described thus far. The distribution was different from either. There was more in bone than in the Rochester experiment, but also much more in RES organs (liver, spleen, bone marrow) and in the "remainder" tissues (skin, muscle, etc.) than in the Berkeley work. Furthermore, as the doses decreased, the fraction in bone decreased, that in the "remainder" tissues increased, and the fraction in RES tissues remained about the same. In the Los Alamos study, much of the thorium in "bone" was in marrow, while that in the University of California, Berkeley, study, at true tracer levels, was in cancellous bone. This showed that surely there were opposing factors at work, e.g., chemical properties, solubility of the salt given, and effects related to the total mass of thorium given and its propensity to form colloids.

Thomas (1961) analyzed these phenomena in detail and added the results of an experiment of his own. This experiment, done at Rochester (Thomas 1957), involved intratracheal administration of ^{230}Th (ionium) + carrier- ^{232}Th in the rat. The form was presumed to be the hydroxide, and the dose was about the same

as in the work of Scott and coworkers, 4 mg/kg. The lung acted like a reservoir much as the injection site did in the Lanz (Berkeley) experiment. A large amount was excreted in feces. But the amount in bone was only about one-tenth of that seen in the Lanz intramuscular injection experiment with tracer ^{234}Th . After an analysis of the numbers of atoms of ^{234}Th versus ^{230}Th present in the skeleton, in the original dose, and in the "reservoir" tissue if there was one, Thomas concluded that solubility at carrier thorium levels and at tracer levels differed by a factor of about five to ten when the material enters from a reservoir with a concentration difference of 10^6 .

These comparisons provided some explanations but left also some puzzling inconsistencies.

At about this time, thorium isotopes had entered the University of Utah experiment with beagle dogs, which we will review in detail in chapter 8. Thorium-228 was introduced into the long-term toxicity work because of its possible role in the radium dial painter experience (see chapter 1). It turned out that this isotope contributed inconsequentially to the toxicity of radium dial paint to the luminizers because of its poor absorption from the gut. But it was kept in the Utah experiment as an opportunity to study not only ^{228}Th but its decay series of daughters. This latter aspect was reported in detail (^{224}Ra , ^{212}Pb , and ^{212}Bi) by Stover et al. in 1965 and will be considered presently.

Let us look first at ^{228}Th itself in the dog (Stover, Atherton, and Mays 1962). At 3.5 yr after intravenous injection of tracer levels of carrier-free ^{228}Th (Rd Th), fully 80% of the retained thorium was in the skeleton. The remaining 20% was widely distributed in the soft tissues, especially liver and kidney. At the outset, liver held about 44% of the injected dose, but it fell by exponential kinetics to about 1% at 1,400 days. No problems of dose-level effects appeared, since even the highest dose was a tracer level, and the behavior did indeed look somewhat like plutonium. (Stover and coworkers compare the chemical and biochemical behavior of ^{239}Pu and ^{228}Th in detail and arrive at an interesting list of similarities and differences between these two tetravalent actinides in the beagle.)

The several symposia and annual reports from the Utah Project (see chapter 8) give retention functions for each of the elements involved in the work. It is worth noting here that the initial skeletal dose rate from ^{228}Th is higher than that from ^{239}Pu or ^{226}Ra by a factor of about four, but it falls off more rapidly so that by one hundred days the difference is a factor of two for ^{239}Pu and about three for ^{226}Ra (Stover, Atherton, and Mays 1962, p. 6).

Meanwhile, the Rochester group was planning inhalation studies with thorium. They faced the dilemma of choosing a dose that would produce effects yet would not have large carrier effects to modify the biochemistry so much that the results would have no bearing on the low levels of exposure associated with permissible occupational exposure. Thomas, Lie, and Scott (1963) decided to extend the work on distribution and excretion patterns using four routes of entry (intravenous, intramuscular, intraperitoneal, and intratracheal) and two levels of ^{234}Th with ^{232}Th carrier, viz., 5.5×10^{-6} g thorium/kg body weight and 6.4×10^{-3} g thorium/kg. The results confirmed and amplified the earlier work. At the lower tracer level, deposition in bone was significant. At the higher level, the thorium acted like a very insoluble substance and showed the properties of particles. After analyzing the work of many others in addition to their own, these workers felt quite confident that many of the puzzling contradictions of earlier studies could be explained. Indeed, thorium deserved to be considered like plutonium at low concentrations. At high concentrations, entirely different

phenomena enter, and these distribution and excretion data have no bearing on occupational exposure situations.

The fraction of thorium in "skeleton" went through a minimum at about 10^{-4} g/kg when the data from the several experiments were plotted together. The increase at lower concentrations represented deposition in cancellous bone; the increase at higher concentrations represented increasing deposition in marrow as an organ of the RES. Figure 4.9 reproduces the schematic of these phenomena taken from Thomas and coauthors. The minimum in bone deposition appears between 10^{-5} and 10^{-3} g thorium/kg injected.

FIGURE 4.9. Percent deposition in the skeleton of rats as a function of the quantity of intravenously injected thorium. (Redrawn from Thomas, Lie, and Scott 1963. Reprinted with permission of Pergamon Press, Ltd., Elmsford, New York, copyright 1963.)

The first actual inhalation experiment was soon done by Boecker, Thomas, and Scott (1963). Water-soluble thorium chloride was used for the exposure aerosol. At early times after inhalation, the material behaved as if it were indeed soluble, and fairly rapid absorption from the lung took place. But this soon ceased, and very little additional absorption occurred. Any further loss from lung was almost entirely by the normal clearance mechanisms for insoluble dusts. In contrast to the work involving other routes, and despite a concentration range from 1.7×10^{-8} to 1.8×10^{-3} g thorium/kg, there was little effect of the dose size per se on the pattern of distribution and excretion. Mostly the inhaled material acted like an insoluble salt, and only about 20% of the lung burden went to bone. But neither did it go to RES tissues! It just remained in the lung

until removed and excreted in feces. Thus, the behavior after injection is not a suitable surrogate for inhalation exposure. (Fortunately, the differences would make any standards based on injection more conservative.)

Boecker (1963) then compared the behavior of inhaled ^{234}Th citrate complex with the thorium chloride used in the earlier inhalation work. This was in order to check their behavior when given by the same route. There were differences. The citrate complex was absorbed from the lungs to a considerably greater extent than was the chloride, but again only for a short period (one to two hours). After that, the two compounds disappeared from lung slowly and at the same rate. There was more in skeleton, liver, and muscle following inhalation of the citrate complex. But again the difference was all due to the initial events. It was as though both compounds were transformed to some common state shortly after deposition and behaved like a single substance thereafter.

Boecker also compared divided with single inhalation exposures. There was no real difference in distribution or excretion whether the exposures were given in two or five installments or in a single administration. The same fractions of the lung burden were absorbed on all regimens.

Unfortunately for the thorium work, Boecker left Rochester to go to the Lovelace Foundation, where he became occupied with other inhalation problems, and Thomas was occupied otherwise. Thus, the Rochester program with ^{234}Th never got extended to the area of effects. The only long-term inhalation toxicity experiment we have is the one already discussed with natural thorium. Should the thorium cycle expand or replace the uranium cycle, relative carcinogenicity to the lungs of tracer levels of thorium will need to be compared to plutonium.

The group at Case Western Reserve University looked early at concentration effects with parenterally administered thorium and came up with results (Mattis 1950) comparable to those described in the paragraphs above. Also a report from the USSR (Kendysh 1966) was in the same vein.

Let us now turn briefly to the behavior in vivo of the wandering daughters from the thorium series. Knowledge of the metabolism of each member of each series is essential for the calculation of radiation dose. Two sources have provided the bulk of the information: the Utah beagle dog experiment and whatever could be gleaned from the Thorotrast patients and other studies on man. We will look first at the beagle dog work. Stover (1981) and Stover et al. (1965) have provided the definitive information on how most of the daughters behave in the beagle. Mays, Haldin, and Van Dilla (1958) addressed the behavior of thoron produced in the ^{228}Th chain, also in the beagle. The 1965 work concentrated on blood and excreta with emphasis on ^{224}Ra , ^{212}Pb , and ^{212}Bi . It was clear that some of the daughter products indeed escaped from the beagle and, of course, these and all of their subsequent decay products did not contribute to dose. But it was concluded that such excretion does not "substantially reduce the potential α -irradiation from ^{228}Th ." Indeed, movement of ^{224}Ra , ^{212}Pb , and ^{212}Bi within the dog probably results in irradiation of many more cells than if they had decayed at the site of ^{228}Th deposition. Equations for the relative movement are provided.

The 1979 work considers the daughter concentrations in blood and excreta, but adds also the disequilibrium in tissue samples (bone, liver, spleen, kidneys). About all that can be said in the space available here is that the microdosimetry of the skeleton subjected to the ^{228}Th chain is "intriguingly complex." Even more sophisticated measuring and modeling are suggested.

Finally, as might be expected from its extremely short half-life (54.5 sec), most of the thoron (^{220}Rn) produced in the beagle body is retained rather than exhaled (Mays, Haldin, and Van Dilla 1958). Thus, there is a little loss (maximum 10%) of members of the ^{228}Th chain by formation of the inert gas. This is quite in contrast to the situation in the ^{226}Ra chain, where a significant amount of the radon is exhaled and lost from the body.

One early bit of evidence from the animal work is important. In the autoradiographic work from Berkeley, done during the war years with ^{234}Th , it was strikingly clear that its microscopic localization in bone was more like that of plutonium than of radium (Hamilton 1947). It was localized on bone surfaces near the zones of most concentrated bone growth.

In a later study, the pattern of distribution in rat liver following intravenous administration of Thorotrast was found to indicate a major cycle in the Kupffer cells and a minor cycle in the hepatic cells (Tessmer and Chang 1967). By light and electron microscopy, they were able to show a multiplicative process in the Kupffer cells; followed by limited degeneration and fibrosis. Being professional pathologists, the authors then tied the experimental findings into effects noted in human liver—a subject for the next major section of this chapter.

The actinium series ($4n + 3$) has received relatively little attention in biomedical research. Los Alamos looked at the toxicology of actinium equilibrium mixture, the individual members were included in the Berkeley work, and a comprehensive analysis of metabolism in the rat was conducted at Mound Laboratory just before it ceased biological research.

All of the essential findings can be gleaned from the summary of a published paper from Mound Laboratory by Campbell, Robajdek, and Anthony (1956), which is excerpted below:

1. Rats injected with Ac^{227} in equilibrium with its daughters (AEM) excreted about 50% of the administered Ac^{227} within three months. The remaining 50% appeared to be retained by the rats almost indefinitely.
2. Ac^{227} which was deposited in the skeleton was not excreted, whereas that deposited in the visceral organs was readily excreted.
3. Ac^{227} deposited in the skeleton remained in equilibrium with its daughters, whereas that in the soft organs was stripped of its daughters.
4. Orally administered AEM is quickly excreted in the feces. Less than 0.1% is retained by the rat.
5. Normal skin is an effective barrier to AEM. Abraded skin allows some passage of Ac^{227} and its daughters into the rat.
6. No appreciable amount of Ac^{227} or its daughters is transferred across the placenta of injected females to their young.
7. Radioactive substances were excreted in the milk of lactating rats injected with AEM. The radioelements responsible for their activity were Ra^{223} (80 to 90%) and Th^{227} . No Ac^{227} was found.

Obviously, the distribution and excretion work with thorium in animals showed the many facets of its behavior and the complexities of trying to arrive at reliable calculations of radiation dose. On balance, the work made the pegging of the $(\text{MPC})_a$ at low values seem much less questionable than when we only had data from natural thorium.

B. Distribution and Excretion of Thorium Isotopes in Man

The characterization of the metabolic behavior of the several thorium isotopes and their progeny in animals was a considerable achievement. But there was the usual question of the extent to which the animal data could be applied to man. Despite the much greater difficulties occasioned by lack of tissue samples and of controlled experimental conditions, several quite satisfactory investigations have been conducted in man.

1. Thorotrast

The principal source has been, of course, the patients who received Thorotrast in the period 1930 to 1950. These have a feature seldom present in retrospective studies on man, i.e., the administered dose was reasonably well known. This was because the injections of Thorotrast as a radiopaque medium were fairly standardized around the world. They have the disadvantage of the passage of frequently long time intervals between injection and study and the frequent presence of illness in the patients. Fortunately, the first disadvantage is almost nullified by the tenacious retention of Thorotrast. We will examine the work of two laboratories in some detail and only refer to the others.

A landmark study was done jointly by John Hursh and associates at the University of Rochester and William B. Looney and associates at the Radioisotope Laboratory of the U.S. Naval Hospital, Bethesda, Maryland (Hursh et al. 1957). This built upon still earlier autoradiographic work of Rotblat and Ward (1953) and measurements by Rundo (1955) and Stenstrom (1941). Stenstrom used both human subjects and rabbits. Hursh et al. used a spectrographic procedure for ^{232}Th much like that used for measuring natural uranium and radioactivity measurements for the other isotopes. They measured tissue distribution and excretion of ^{232}Th and ^{228}Th , ^{224}Ra and ^{228}Ra . They also used an external gamma counting technique to correlate with the excretion measurements and employed two human subjects who had received Thorotrast not too long before the measurements were made. These provided data on excreta for 17 to 236 days, respectively. There were autopsy tissues from four Thorotrast patients including the two just mentioned. The excretion measurements were updated by Hursh at a symposium of the New York Academy of Sciences (Hursh 1967).

The findings paralleled those we have already seen in the animal work, i.e., very slow excretion, long retention (biological half-life over four hundred years), slightly more rapid excretion of ^{228}Ra , and considerably more rapid excretion of ^{224}Ra . The calculated tissue doses from deposited Thorotrast were highest in liver and spleen, a factor of ten lower in bone marrow, and still lower in lung. There was no question but the distribution of dose from deposited Thorotrast and its daughters was quite different from that of radium and its progeny. The dose to skeleton was low and mostly to the bone marrow.

An unexpected phenomenon was the behavior of ^{224}Ra . At early times, it behaved like ^{226}Ra , i.e., like a freely diffusible ion. But at later times, much less was excreted than expected, and the ^{224}Ra acted as though it were entrapped in the large colloidal aggregates of Thorotrast.

A second relatively major effort came from the Radiological Physics Division at Argonne National Laboratory and the Department of Research and Isotopes of the International Atomic Energy Agency in Vienna (cf. the work of R. M. Parr and R. A. Dudley).

The early reports were ANL reports where Marinelli, Miller, Lucas, Parr, and colleagues described the translocation of thorium daughters to bone (ANL

Report-5689, 1957; ANL Report-5967, 1958; ANL Report-6398, 1961). This was followed by a very complete analysis by Parr, Lucas, and Griem in the June 1969 annual report (ANL-7615). Some of this work was published in the proceedings of the symposium held by the New York Academy of Sciences^(a) (Parr 1967; May, Marinelli, and Corcoran 1967). There was a complete recapitulation of the dosimetry by Dudley (1967).

The ferreting out of the activities of seven nuclides in vivo in six human patients and nine experimental animals rivaled in scientific detective work the original depiction of the thorium series. The nanocuries per organ and the alpha-ray dose were summarized by Parr and coworkers (1969) and by Dudley. These are shown in section B 3 below.

Similar results have been obtained in many other laboratories in the United States and abroad. Special mention should be made of the study by Cohn, Gušmano, and Robertson (1967) at Brookhaven National Laboratory, since they were able to deduce doses to liver and spleen entirely by whole-body counting techniques. Maletskos et al. (1969) at the Massachusetts Institute of Technology (MIT) injected soluble ^{234}Th in five elderly subjects and gave oral doses to six similar subjects. They confirmed the very small absorption of thorium from the gastrointestinal tract and that the main route of excretion was feces. Many of the epidemiologic studies abroad involved also measurements of dose in vivo. The work came from Denmark, West Germany, Austria, Czechoslovakia, and Japan, among others, as indicated in the table of contents of symposia (e.g., Lake Geneva, Wisconsin, [Rundo, Failla, and Schlenker 1983] and IAEA symposia), as well as many papers in the journal, *Biophysik*, and in *Health Physics*.

At the microscopic level, the problems raised by the autoradiographic work in animals were pursued in the human material. Jee et al. (1967, 1969) at Utah found the activity of ^{228}Th to be much higher in spongy bone than in compact bone from two Thorotrast patients and a large dog. They reconstructed the dose to the entire skeleton as well as the areas examined by careful track counting and some brave extrapolations. They had only one sample of bone from one patient and a few samples from the other. Nevertheless, the calculated total activity in skeleton (1% to 2% of injected dose on the basis of ^{232}Th) was comparable to that found by the more direct means of whole-body and sample radioactivity counting. Probably the most important contribution of work such as this, and there is much more than we can quote here, relates to microdistribution. The ^{232}Th and daughters were diffusely, but unevenly, distributed with occasional "hot spots." Macrophages loaded with alpha activity were frequently the source of the hot spots, and they were seen sometimes adhering to the endosteum, especially when the burden time had been long. Ratios of hot spot to diffuse (average) distributions were over ten for cortical bone, much less for spongy bone.

There is no doubt that quantitative autoradiography has a place in internal emitter research. But one wishes in the case of the Thorotrast problems that it were as good for soft tissues as for bone. Qualitatively, autoradiographs of tissues like liver and spleen show the presence of many, sometimes very large, aggregates whose significance depends upon the amount of self absorption,

(a) Some of the same work and studies abroad were presented in a symposium in Vienna in 1965; which we will discuss in the next section.

their location, and the true importance of microdose distributions. But only recently have the techniques been as good for soft tissue as for bone.

2. Other Sources of Data on Man

An important compilation on thorium in human tissues from sources other than Thorotrast is found in a Nuclear Regulatory Commission report prepared by the New York University (NYU) group with help from Geno Saccomanno in Grand Junction, Colorado (Wrenn et al. 1981). The principal findings in this report were summarized at the Lake Geneva Symposium on Radium and the Actinides in 1981 (Ibrahim et al. 1983).^(a) For these, twenty-two sets of tissues were obtained at autopsy from persons residing in Grand Junction, Colorado, or Washington, D.C. There was no known occupational or unusual environmental exposure to thorium in either population, except for one uranium miner and one hard-rock miner. They measured ^{228}Th , ^{230}Th , and ^{232}Th in each case.

Consistent with thorium's reputation for complexity, the results were different for different isomers and between the two locations. This can be seen in table 4.5, taken from the published paper (Ibrahim et al. 1983).

The work suggested that nonmining residents living in the vicinity of uranium mill-tailings (Grand Junction) do not have elevated ^{230}Th concentrations in their lungs compared to residents of Washington, D.C., but the concentration in bone was "just significantly higher" in the Grand Junction residents.^(b)

TABLE 4.5. Order of Concentrations of Three Thorium Isotopes^a in Autopsy Tissues from Two Small Populations

Isotope	Location	Order of Decreasing Concentration
^{228}Th	Grand Junction	Lymph nodes > bone > lung > kidney > liver
	Washington, DC	Lymph nodes > bone > lung > kidney > liver
^{230}Th	Grand Junction	Lymph nodes > bone > lung > kidney > liver
	Washington, DC	Lymph nodes > lung > bone > liver > kidney
^{232}Th	Grand Junction	Lymph nodes > lung > bone > kidney > liver
	Washington, DC	Lymph nodes > lung > bone > liver > kidney

Source: Reset from Ibrahim et al. 1983. Reprinted with permission of Pergamon Press, Ltd., Elmsford, New York, copyright 1983.

Wrenn, Singh, and Saccomanno (1983) also presented radiochemical analyses for uranium and thorium isotopes in the lungs of seven uranium miners obtained at autopsy. The combined radiation dose rate due to the three long-lived radionuclides, ^{238}U , ^{234}U , and ^{230}Th , was calculated to be from 2.5 to 14.2 mrad/yr, mean 9.6 mrad/yr. Only a portion of this dose would come from the thorium.

(a) Some of the NYU investigators (Wrenn and Singh) had by the time of publication moved to the University of Utah. The conference was held in 1981.

(b) There were also measurements on Grand Junction soil, but this did not explain the tissue results.

Tissue contents of thorium workers have been reported but do not contribute much to an analysis of dose. Further work is under way.

One case of an accidental puncture wound with ^{227}Th occurred at ANL and was reported in a publication by Gustafson, Marinelli, and Hathaway (1957). There was a fairly complete study of elimination and retention of both the ^{227}Th and its decay product, ^{223}Ra . The case is complicated by the fact that the injection site was excised surgically, and there was treatment with a chelating agent. Nevertheless, and discounting these complications, it appears that the ^{227}Th is more mobile. It cannot be determined whether or not this extra mobility is a property of the isotope or of the low concentrations involved, or both. The animal work would clearly favor the second explanation.

3. Recapitulation

In view of the tortuosities of the thorium series and the many points for useful comparison with radium and plutonium, recap of the information on distribution and excretion might be beneficial.

A clear summary is given by Mays et al. in the Utah symposium published in 1969. This bears on the behavior of carrier-free ^{232}Th deposits in the beagle and relations to plutonium. The summary follows:

About 70% of the carrier-free ^{228}Th deposits in the Beagle skeleton when injected intravenously in citrate solution. Microscopically the deposition on bone surfaces appears similar to that of ^{239}Pu . Both ^{228}Th and ^{239}Pu are retained tenaciously in bone. However, they differ in radiation characteristics. Whereas the long 24,000 year physical half-period of ^{239}Pu gives a fairly constant skeletal dose-rate throughout life (see Figure 1), and 1.9 year physical half-period of ^{228}Th causes over half of the life-span dose to be delivered during the first 2 years, by 10 years virtually all of the injected ^{228}Th has decayed away. The soft-tissue range of ^{239}Pu α -particles is 35 microns, whereas it varies from 38 to 82 microns for ^{228}Th and its daughters. Therefore, the α -particles from the ^{228}Th series in bone reach out farther into the marrow.

The short-lived daughters of ^{228}Th create special complications. When ^{228}Th decays to ^{224}Ra , a fraction of this radium isotope reaches the circulation. Part is excreted, and part redeposits such that in bone the total ^{224}Ra activity is about 90% of that of ^{228}Th . The highest skeletal concentration of the redepositing ^{224}Ra is in the active sites of new bone formation. This occurs continually, so that all new bone formed after ^{228}Th injection has an enhanced probability of being irradiated during its critical time of formation. The next daughter ^{220}Rn (thoron) is a noble gas. Its short 56 second half-period prevents significant loss from the skeleton, but may allow some diffusion into fat-containing cells in the marrow. Thoron is about 15 times more soluble in fat than in blood. A small amount of ^{212}Pb tags blood cells and thus delivers low doses to all body tissues. The combined escape of ^{224}Ra , ^{220}Rn (thoron) and ^{212}Pb is such that in bone the ^{212}Pb activity is about 86% that of ^{228}Th . Some ^{211}Bi (the next daughter) is taken up from the blood by the kidney. In the liver the activity of ^{212}Pb is slightly higher than that of ^{224}Ra , which is about 30% higher than that of ^{228}Th .

The soft-tissue depositions of ^{239}Pu and ^{228}Th are quite different, despite their similar-appearing deposition in bone. A year after ^{239}Pu injection, about 20 to 30% of the injected ^{239}Pu is retained in the liver, but the retention is only about 0.2% in the kidneys and 2 in all the other tissues. In contrast, the 1-year biological retention of ^{228}Th is about 3% in the liver, 1 to 2% in the kidneys and 8% in the remaining soft tissues. The dose to the kidneys from ^{228}Th and its daughters is about 10 to 30% of that to the skeleton. A characteristic and severe damage to the kidney termed

"radiation nephritis" has been observed in high-level ^{228}Th dogs, as well as significantly increased values of inorganic phosphorus in the serum.
(Quoted with slight modification from Mays et al. 1969)

Some additional thoughts for the comparison of thorium and plutonium are emphasized in Betsy Stover's paper at the 1979 Utah conference already cited. Thorium exists only as the tetravalent ion in aqueous solution, whereas plutonium has several valence states, four of them moderately stable. Toxicological work has arbitrarily been arranged to have the plutonium in the tetravalent state. But it was sometimes in other states or transformed to them.

The nearest we can come to a similar recapitulation for the metabolism of thorium-series isotopes from Thorotrast is to reproduce the calculated organ contents in the steady state and alpha-ray dose from the last and most complete of the ANL studies (Parr, Lucas, and Griem 1969). These are shown in tables 4.6 and 4.7. Included in table 4.7 are these authors' comparisons of estimated organ dose rates among the several studies.

TABLE 4.6. Thorium-Series Activities and Mean Dose Rates in Various Organs (50 ML Thorotrast Injected Intravascularly)

Organ	Wet weight, g	Nanocuries in Organ at Steady State							α -ray Dose from all Isotopes, Rad/year
		^{232}Th	^{228}Ra	^{228}Th	^{224}Ra	^{220}Em and ^{214}Po	^{212}Pb	^{212}Bi	
Whole Body	70,000	1,250	625	625	580	530	525	525	
Liver	1,700	860	430	390	270	215	135	90	71
Spleen	150	210	105	95	67	54	35	25	168
Red bone marrow	1,500	100	25	30	20	40	40	40	18
Lungs	1,000	10	5	3	3	30	30	30	13
Blood	5,400	0	0	0	3	100	55	55	6
Kidneys	300	1.3	0.3	0.6	0.5	0.4	2	4	3
Skeleton (marrow-free)	7,000	15	25	30	50	48	45	45	3

Source: Modified from Parr, Lucas, and Griem 1969.

It is quite obvious how much higher the dose is to soft tissue and how much lower it is, relatively, to marrow-free skeleton when the thorium-series isotopes are produced in vivo from colloidal deposits of thorium dioxide. This may seem a rather obvious conclusion, hardly worthy of the intense effort necessary. But note that it is quantitative and far beyond a simple declaration of facts. It is essential for dose calculations.

TABLE 4.7. Summary of Estimated Dose Rates to Organs of Thorotrast Patients

Author	Year	Mean Organ Dose Rate ≥ 20 Years After 50 ml Thorotrast Intravascularly, rad/year(a)						
		Liver	Spleen	Red Bone Marrow	Kidney	Lung	Skeleton	Blood
Parr et al.	1967	71	168	18	3	13	3	6
Hursh	1965					4-9		
Muth	1965					4-7		
Kaul	1964,65	65	145	30			2	
Rundo	1958	68	178	14-61		5		1
Hursh et al.	1957	78	78	8		3		
Reynolds et al.	1957						4-9	

(a) Dose rates reported by the different authors in most cases do not refer to 50 ml of Thorotrast. The values quoted here have been normalized on the assumption of proportionality between dose rates and volume of administered Thorotrast, though this is not strictly true because of differences in self-absorption of the radiation.

V. Effects of Thorium-Series Isotopes

A. The Thorotrast Saga

The thousands of patients who received Thorotrast in the practice of radiology over two decades constitute the fourth major human population exposed significantly to the biological action of alpha particles produced by radioactive decay of the heavy elements. The others are, of course: (1) the radium dial painters, chemists, and patients discussed in chapter 1; (2) the German population that received the short-lived ^{224}Ra as a therapeutic nostrum, also described in chapter 1; and (3) the uranium miners exposed to radon and its daughters, discussed in chapter 3. We could add the MED uranium workers, but they are essentially a silent group thus far except for chemical toxicity (see chapter 2). The plutonium workers of World War II are a sixth potential population, but as we will see in chapters 8 and 16, they too have been silent to date, even though study has been extensive. Thus, there are four populations that are providing definite evidence of effects out of a total of six.

Some concerns were expressed for long-term effects of Thorotrast relatively soon after its use began in earnest. Cancer in animals was reported as early as 1933 by Oberling and Guérin and in 1936 and 1938 by Selbie, who confirmed the French work. Andervont and Shimkin (1940), at the National Cancer Institute, extended the work with particular concern for lung tumors. They found

find subcutaneous sarcomas and one hemangioma. Selbie declared in his *Lancet* paper: "Thorotrast should never be introduced into the human body because of the danger of inducing tumor formation."

Other authors predicted that cancer would appear in man on a priori grounds, i.e., the long retention time and the fact that the radiation was from alpha particles.

These warnings did not stop the use of Thorotrast, although it did begin to decline. The biggest jolt came when the American Medical Association Council on Pharmacy and Chemistry removed it from their approved list. But this was just before World War II, and either the word did not spread or radiologists were too preoccupied to find substitute radiopaque media. It appears that its use declined considerably during the war but did not actually cease until about 1950.

In the early years, many who questioned the use of Thorotrast were told how low its radioactivity was compared to that of ^{226}Ra , which was then the only other radioactive material in general use in medicine and industry, and that the thorium in Thorotrast could not possibly cause radiation damage. Those making such statements neglected the large differences in mobility between radium and thorium. Also, they neglected the fact that ^{232}Th is the parent of a chain of radioactive materials of very different characteristics from the daughter products of ^{226}Ra .

The end of World War II brought the opportunity to focus down on Thorotrast and to demonstrate its effects. As it became apparent that very sizeable populations carrying Thorotrast existed in several parts of the world, a series of conferences and symposia were convened, and the dimensions of the problem gradually unfolded. The story is still far from complete in terms of the desired dose-response relationships. But the fact emerged that cancer of soft tissues, particularly liver, was a serious and not infrequent long-term effect. Leukemia incidence was also increased, but not so markedly. Bone cancer incidence was not materially increased.

The major studies are distributed throughout the world, and, despite the general need for this book to emphasize U.S. contributions, we will consider the picture in many countries.

Three large European surveys are in progress. The oldest is in Denmark, under the career-long tutelage of Mogens Faber at the Finsen Laboratory in Copenhagen. The most recently organized survey is the West German project, with which we associate, among others, the names Muth and Kaul. Finally, there is a fairly homogeneous population in Portugal, with which we associate especially the name da Silva Horta.

A Japanese population and study was reported by Tsukamoto (National Institute of Radiological Sciences) and is being carried forward by his colleagues. There is also some follow-up work in England appearing from the Institute of Cancer Research at Sutton, Surrey.

Groups in the United States interested in Thorotrast effects are somewhat scattered. Norman Telles and others worked with the Massachusetts General Hospital, MIT, and Harvard researchers including Shields Warren, and U.S. Public Health Service Representatives. Looney (1960) contributed some patient experience from the U.S. National Naval Hospital. This was used in part in the Rochester dosimetry work already discussed (Hursh et al. 1957). The Argonne National Laboratory group, likewise concentrating on dosimetry, got patient records and samples from the Mayo Clinic, among others. The Salt Lake City

group, which got involved in dosimetric research primarily because of Mays's interest in ^{224}Ra , has been involved in several reviews of the entire effort.

Fortunately, these efforts have been very well documented in a series of symposia and associated monographs, and we can bypass the developmental stages and look at the status as of approximately the midseventies.

First, the symposia and monographs are given in approximate chronological order:

1. The Dosimetry and Toxicity of Thorotrast. Joint IAEA-WHO meeting, Vienna, 4-7 October 1965. Published as IAEA Report 106 in 1968.
2. Distribution, Retention and Late Effects of Thorium Dioxide. A meeting at the New York Academy of Sciences in 1965, published as Vol. 145, Art. 3, Pages 523-858 of *Annals of the New York Academy of Sciences* dated December 11, 1967.
3. International Symposium on Biological Effects of ^{224}Ra and Thorotrast. Held at Alta, Utah, 21-23, July 1974. Published as Vol. 35, No. 1 of *Health Physics*, July 1978.
4. A symposium at Copenhagen with a series of papers, which may or may not comprise the entire proceedings, published in *Environmental Research*, Vol. 18, 1979.

Since the last meeting may or may not be generally available, a selection of titles from the pertinent issue of *Environmental Research* is given herewith:

1. Thorotrast Dosimetric Study in Japan. Y. Kato, T. Mori, and T. Kumatori, National Institute of Radiological Sciences, Chiba, and Kanagawa Prefectural Junior College of Nursing and Medical Technology, Yokohama. *Environmental Research* 18: 32-36 (1979).
2. Twenty-Eight Years of Continuous Follow-up of Patients Injected with Thorotrast for Cerebral Angiography. Mogens Faber, The Finsen Laboratory, The Finsen Institute, Copenhagen. *Environmental Research* 18: 37-43 (1979).
3. Epidemiological Follow-Up Study of Japanese Thorotrast Cases. T. Mori, T. Maruyama, Kanagawa Prefectural College of Nursing and Medical Technology, Yokohama; Y. Kato, and S. Takahashi, National Institute of Radiological Sciences, Chiba; and Hamamatsu University School of Medicine, Hamamatsu. *Environmental Research* 18: 44-54 (1979).
4. Prospective Epidemiological Study of Thorotrast-Exposed Patients in Portugal. Luiz Cayolla da Motta, National School of Public Health, Secretariat of State for Health, Lisbon, Portugal; Jorge da Silva Horta, Institute of Pathology, Faculty of Medicine, Lisbon; and Maria Helena Tavares, Hospital of Santa Maria, Lisbon. *Environmental Research* 18: 152-172 (1979).
5. Statistical Analysis of Japanese Thorotrast-Administered Autopsy Cases. T. Mori, Y. Kato, T. Shimamine, and S. Watanabe, Kanagawa Prefectural College of Nursing and Medical Technology, Yokohama; National Institute of Radiological Sciences, Chiba; University of Tokyo School of Medicine, Tokyo; and University of Hiroshima School of Medicine, Hiroshima. *Environmental Research* 18: 231-244 (1979).

In addition, an earlier description of the Portuguese study was presented in Volume 8 of the same journal:

Thorium Dioxide Effects in Man: Epidemiological, Clinical, and Pathological Studies (Experience in Portugal). J. da Silva Horta, L. Cayolla da Motta, and

Maria Helena Tavares, Department of Pathology, Faculty of Medicine, Lisbon. *Environmental Research* 8: 131-159 (1974).

Many individual reports were given as parts of IAEA symposia on more general subjects, at the Atoms for Peace Conferences, and festschrift events. A good summary of the findings to 1978 is shown in table 4.8, modified from Mole's paper (1978).

TABLE 4.8. Tissue Dose and Tumour Excess in Thorotrast Patients Compared with Risks from Other Examples of High-LET Radiation

Tissue of Origin or Type of Tumour	Average Tissue Dose 30 yr After 25 ml. of Thorotrast*	Excess Tumours in 4000 Subjects	Induction per rad per 10 ⁶ Persons After 30 yr	
			Thorotrast α -particles	Other Sources of High LET Radiation
Liver	750 rad	245	80	88: Faber for Thorotrast.
Lung (bronchi)	60-620	none definite		300: from BEIR I Table p. 150 giving 1 case 10 ⁻⁶ per year per rem for miners exposed to ²²² Rn with RBE equal to 10 for α -particles.
Bone endosteum	480 (all sources) 210 (translocated)	2-6	1-3 2-7	10: Speiss and Mays for ²²⁴ Ra in adults and an endosteal/av. skel. dose ratio of 9.

The interest abroad in the Thorotrast story has gradually kindled interest in the United States, primarily in the form of helping with dosimetry and being sure the data were considered by national organizations, such as the National Academy of Sciences and the NCRP. No organized epidemiologic survey has yet been put together to study the U.S. population of Thorotrast patients.^(a) The coordinated in-depth epidemiology remains primarily in the European centers and Japan.

(a) There is no easy explanation for this hiatus. Perhaps the more centralized cohesive populations in Europe are better suited. Perhaps a higher percentage received Thorotrast.

The production of liver cancer in the Thorotrast patients struck a responsive chord in the Utah group, since they were beginning to see liver cancer in the long-term beagle dogs that had received actinide elements. This has led Mays, in particular, to a deep interest in the subject and some calculations of risk. His summaries of the Thorotrast findings (Mays 1979) are pertinent to this discussion. In table 4.9, we see his summary of the European population size and liver cancer incidence. In table 4.10, we see a breakdown of the liver tumors by country and by type of cancer.

TABLE 4.9. Thorotrast Patients Surviving at Least 10 Years After Intravascular Injection

Country and Year of Last Follow Up	Cases of Liver Cancer	Traced Patients Surviving at Least 10 Years	Person-yr at Risk from 10 yr Post Injection to Death or Last Contact
Germany, 1977	176	1,733	28,424
Denmark, 1977	50	646	12,274
Portugal, 1974	75	667 ^a	12,673 ^a
Total	301	3,046	53,371

^a The fraction of the Portuguese patients surviving at least 10 years, and their average time to death or last contact, was considered similar to that documented for the Danish patients. In both countries, suspected brain diseases were the main reason for the intravascular injection of Thorotrast (80% in Portugal and nearly 100% in Denmark).

Source: Modified from Mays 1979.

TABLE 4.10. Liver Cancers in Thorotrast Patients (at Latest Detailed Tumor Classification)

Types of Liver Cancer	Germany as of 1975	Denmark as of 1977	Portugal as of 1974	Japan as of 1975	Total
Angiosarcomas ^a	37	20	19	20	96
Bile-duct carcinomas	48	15	11	57	131
Hepatic-cell carcinomas	21	15	2	10	48
"Liver" carcinomas ^b	20	0	0	0	20
Unspecified ^c	14	0	43	6	63
Total					358

^a In the general population the most frequent types of primary liver cancer are hepatic-cell carcinomas and bile-duct carcinomas. Angiosarcomas are extremely rare, except in persons exposed to Thorotrast, arsenic, or vinyl chloride.

^b Either bile-duct carcinoma or hepatic-cell carcinoma.

^c Fatal, but not classified histologically, except for one case of reticulosarcoma in the Portuguese series.

Source: Modified from Mays 1979.

Using 25 rad/yr as the dose from 26 ml of Thorotrast, Mays gets 1,334,275 person-rad for the data in table 4.9. After some further calculations and debate on what fraction of the total radiation dose is wasted (i.e., occurs after the cancer has been initiated), Mays calculates a rounded risk figure of 300 liver cancers/ 10^6 person-rad of alpha radiation. It will be noted that this is considerably higher than Mole's slightly earlier estimate (table 4.8). This and other discrepancies require further work for adjudication.

Despite what appear to be large populations and long observation times, Mogens Faber considers that the work must continue to a population size of 10,000 to 20,000 and an observation period of at least twenty-five years (Faber 1968). To accomplish this may require a coordinated international effort.

The primary lesson to be learned from the Thorotrast cases is not to forget that radionuclides that seek soft tissue can be of as much concern as the bone seekers if they are markedly insoluble, have very long residence times, and especially if they have a family of wandering daughters.

A nagging complication in the Thorotrast work is the question of chemical toxicity, particularly in the liver. Thorotrast is not pure thorium dioxide. It contains some chemical additives to help preserve the colloidal state, etc. There is no series of cases with pure colloidal thorium dioxide of sufficient magnitude to act as a control for the Thorotrast observations. Some investigators are not even convinced that the toxicological research with natural thorium can be applied to long-term exposures, despite the indications that it is almost inert chemically. Much needed is a carefully designed experiment using some other radionuclide with radiation properties comparable to those of the thorium isotopes in Thorotrast but without the additives and other complexities of Thorotrast. Such an experiment is under way, using animals, at the University of Utah with a surrogate for thorium (americium). Preliminary results indicate no effect that cannot be accounted for by the radiation dose.

B. The Effects at Tracer Levels and of the Shorter-Lived Isotopes

The effects story with noncolloidal preparations of thorium isotopes, i.e., relatively low concentrations and the shorter-lived isotopes, has been largely an American enterprise. The effects follow what might be expected from the metabolic behavior described in section IV. The major effect, except at early times, is the *induction of bone cancer*. The information is largely from animal experiments.

1. The Utah Beagle Dogs

The major portion of our information on effects of the shorter-lived thorium isotopes comes from the long-term experiment with beagle dogs at the University of Utah to be described in detail in chapter 8. Thorium-228 was introduced, as discussed earlier, because of its possible role in the illnesses of the radium dial painters. All levels were sufficiently low to avoid colloid formation in substantial amount. The injection route was intravenous.

Hematological effects at the "3 level" of ^{228}Th ($0.3 \mu\text{Ci/kg}$) were comparable to those of ^{226}Ra , ^{239}Pu , ^{228}Ra , and ^{90}Sr at the "5 level," i.e., $10.35 \mu\text{Ci/kg}$, $2.88 \mu\text{Ci/kg}$, $8.47 \mu\text{Ci/kg}$, and $97.48 \mu\text{Ci/kg}$, respectively (Dougherty and Rosenblatt 1971), an indication of high effectiveness.

As the bone-tumor incidence unfolded, there was no doubt the ^{228}Th was very effective indeed. As seen in the relative biological effectiveness plot given in

chapter 8 (figure 8.8B), ^{228}Th topped the list in producing death from osteogenic sarcoma in the beagles. In the summary (Mays et al. 1969) quoted in part at the end of section IV, we see some of the possible reasons for this special effectiveness. Thorium-228 had an effectiveness relative to radium of about eight at the "1.5 and 1" levels, as high as nineteen at the "2" level, and about the same as ^{239}Pu , i.e., about six, at the lower levels. (a)

By the time of the twentieth anniversary symposium of the Utah project, they felt they had enough data to plot a dose-response relationship and to estimate risks (figure 4.10). This was published in an annual report in March 1970 and by Mays and Lloyd (1972) in the symposium proceedings. The summary data are shown in table 4.11. Stover (1979) presented an update of the figures at the Snowbird, Utah, symposium (table 4.12). This gives calculated total radiation dose to the skeleton in rad, an updating of the occurrence of osteosarcoma, and the percentage life-span shortening. These results from Utah bring us full circle back to the maximum permissible concentrations for Th-nat and ^{232}Th discussed in section III B. Certainly the shorter-lived ^{228}Th is a very effective carcinogenic agent in bone. Conservatism dictates consideration of exposure limits comparable to plutonium for the progenitor nuclides, ^{232}Th or Th-nat, when exposure is prolonged.

FIGURE 4.10. Thorium-228 dose-response in beagles injected intravenously with monomeric ^{228}Th in citrate solution. The indicated linear relationship predicts 0.7 sarcoma cases among the six dogs that have died without bone tumors at the 16- and 47-rad levels. (Redrawn from Mays and Lloyd 1972. Reprinted with permission of J. W. Press, Salt Lake City, Utah, copyright 1972.)

(a) These "levels" are given in detail in table 8.4, chapter 8. The ^{228}Th levels are shown in table 4.11.

2. Other Animal Experiments

Only a few other reasonably complete effects studies of short-lived bone-seeking thorium isotopes are ready for quoting. One is a German study (Luz et al. 1976). It demonstrated a variety of effects in mice.^(a) They were primarily interested in the ^{224}Ra story, but added ^{227}Th for comparison. They used female mice and gave single or multiple injections of ^{224}Ra and single injections of ^{227}Th .

(a) There were earlier preliminary reports.

At the higher doses, ^{227}Th caused leukemia, which became a primary cause of early death, and also some lesions of the jaw. The incidence of osteosarcoma was considerably higher per rad for ^{227}Th than for ^{224}Ra . There are differences in the anatomical location of the osteosarcomas, with more in the head region at the higher doses.

Some benign tumors (ossifying fibromata) of the jaws also occurred. For these, ^{224}Ra was more effective than ^{227}Th .

There is not much that can be said in explanation of these results, particularly the differences between ^{224}Ra and ^{227}Th . They illustrate amply the greater effectiveness of short-lived isotopes of thorium (and also of radium), presumably because their energy is expended while they are still on or near bone surfaces. There was also early German work on the distribution of thorium to the RES (Engels, Maurer, and Niklas 1949).

Another set of experiments ready for discussion was done in the USSR. This included distribution and excretion, acute toxicity, long-term effects, and detailed examination of the clinical condition of the animals. The work can be found in two translation volumes: Vol. 4 in the series entitled *The Toxicology of Radioactive Substances*, edited by Letavet and Kurlyandskaya (1966) and the large volume edited by Moskalev (paper by Kendysh and Lebedeva [1966] and the one by Kendysh on metabolism already cited). As usual, the USSR work goes into extensive detail on functional changes as well as conventional gross and microscopic pathology. The doses were about 10 mg thorium/kg for single intratracheal administration, 100 mg/kg in intraperitoneal administration, or once weekly up to 1,000 mg/kg. The test animals were rats and rabbits.

Phagocytic function of the RES was clearly depressed after thorium administration as measured by half-life of ^{198}Au in blood and its build-up in spleen and liver. The effect began early and persisted for about a year. The excretory function of the liver, as shown by ^{131}I -labeled rose bengal, was reduced as measured by build-up in the liver and markedly increased half-life. Hepatic blood flow was slowed.

The morphological changes included aggregations of thorium, granulomatous lesions with giant cells containing thorium particles, and vascular changes. Blood changes ranged from early anemia and reticulocytopenia to later leukocytosis.

In general, the intratracheal route of entry was more damaging than the intraperitoneal.

The USSR investigators point out that their doses correspond to only 0.001, 0.01, and 0.1 $\mu\text{Ci/kg}$, and damage is extensive, while plutonium at 0.3 $\mu\text{Ci/kg}$ "does not lead to the development of morphological changes in chronic experiments." On this basis, they conclude that some of the effects of thorium must be due to chemical toxicity. (At that time, the effects of plutonium at the level of 0.3 $\mu\text{Ci/kg}$ had not yet been described.)

In the series of papers in the volume by Letavet-Kurlyandskaya, the range of doses was from 2 to 200 mg/kg; soluble and insoluble compounds were compared, and acute toxicities were determined as well as the long-term effects. Thorium nitrate was the most toxic of the soluble compounds (about 300 mg Th/kg LD_{50}^{30}) with thorium chloride considerably behind (approximately 600 mg Th/kg LD_{50}^{30}). Thorium dioxide was toxicologically inert by comparison. The behavior of thorium dioxide in rat tissues and organs is extensively documented in the first chapter by Syao-Shan (Letavet and Kurlyandskaya 1966).

An interesting clinical observation is the gradual fall in arterial pressure beginning at about nine months after administration. At twelve months, it was lower at 2 mg/kg and 200 mg/kg than at 20, 300, 400, and 1,000 mg/kg. This is a unique observation not mentioned in the studies from other countries. The authors cite studies of thorium workers, which also indicated hypotension and attribute the changes to "disturbance of autonomic regulation."

C. Thoron

It is natural to wonder about the dosages and effects of inhaled thoron by analogy to the effects of inhaled radon. There have been no animal experiments for the obvious reason that thoron (^{220}Rn) has a half-life of only 54.5 sec. Likewise, there is no human epidemiology. Yet, calculations indicate the possibility of exposures to thoron from both thorium metal and thorium ores in storage.

Blanchard and Holaday (1960) at Salt Lake City pursued an analysis very similar to that we saw for radon and its daughters in chapter 3, except that the data were derived from theory and could not be checked by experiment. Duggan (1973), at the National Radiological Protection Board of the United Kingdom, engaged in a similar exercise and made some suggestions for hazard analysis. The results are not like the radon story. The dose from the daughters of radon is much larger (in this case by a factor of seven hundred) than the dose from thoron. Ventilation can play a major role in the fraction of equilibrium attained, but in contrast to the situation with radon, even in quiet air, the ratio of "ThC" to "ThA" is about 0.01 because of the relatively long half-life of "ThB."^(a) Doses to lungs and bronchi from exposure to $10\ \mu\text{Ci}$ of thoron in equilibrium with its daughters could be: from thoron, 4.9×10^{-4} rem/wk to the lungs and 9.5×10^{-4} rem/wk to the bronchi; from the inhaled daughters, 0.35 rem/wk to lungs and 8.7 rem/wk to the bronchi. The latter are obviously not insignificant doses. But internal emitter toxicology efforts have not been extended to significant effects work with thoron.

The nearest we have come to biological studies has been in collection of exhaled thoron. Hursh and Lovaas (1963) describe an ingenious device for measuring thoron exhalation. The gas is collected in a spirometer and then, after passage through a CO_2 and water-vapor trap, enters directly onto a cooled charcoal-particle-covered plate, which is close to a zinc-sulfide-coated disc and a 5-in. photomultiplier tube. Hursh and Lovaas refer also to earlier collection and measurement systems devised by Aub et al. (referred to in chapter 1) and Rundo, Ward, and Jensen (1958). They made measurements of thoron exhalation from two Thorotrast patients and indicate other uses for the system.

Despite the relatively high theoretical doses from inhaled thoron daughters and likely exposures in industry, no systematic investigations of thoron effects in industry have come to the attention of this author. In comparison to the Thorotrast problem, and other members of the thorium series, exposure to thoron and daughters is probably of much less significance.

(a) "ThA" is ^{216}Po , "ThB" is ^{212}Pb , and "ThC" is ^{212}Bi according to the old terminology. This description is no longer used.

VI. Summary and Commentary

This last chapter of the series concerning the naturally occurring radioactive materials considers two elements of importance from the standpoint of health. The other naturally occurring elements are considered below the limits for health concern under normal circumstances.

Polonium, most of whose isotopes are alpha emitters, has had important uses in the atomic energy field and in many devices such as static eliminators. It has never had therapeutic applications. Thorium, which is really a generic name for a large number of isomers, has had much use in industry, e.g., it has been used in the manufacture of gas lamp mantles; a thorium cycle is proposed for nuclear energy to stand beside, perhaps replace, the uranium cycle; and thorium was used extensively in medicine as a component of a radiopaque medium called "Thorotrast."

A. Polonium

It should be mentioned in passing that two of the most energetic and important daughter products of radon are isotopes of polonium. Thus, the radon daughter problem is, in part, a polonium problem. However, it is the longer-lived isotope, ^{210}Po , that has received the most biomedical study.

Polonium contrasts with most of the alpha-emitting radionuclides considered thus far, except radon, in that it does not concentrate in bone to any appreciable extent (unless formed in situ by the decay of ^{210}Pb). It tends to localize in soft tissues. It shows particular propensity to concentrate in elements of the RES due, in part, it seems likely, to its tendency to form radiocolloids. Although the tissue distribution is far from uniform, it is much more like whole-body exposure than that of the bone seekers. Only radon is more like whole-body exposure, but it has an inconveniently short half-life and many complicating decay products. Thus, polonium has been useful for determining generalized soft-tissue effects of alpha particles. They have turned out to be quite different from those of the bone seekers.

Although a small amount of work has been done on polonium in humans, the bulk of the biomedical research has involved animals. The original center was in Lacassagne's laboratory in France. During World War II, the most extensive work was at the University of Rochester, with the addition of some work at Chicago in the latter part of the war years. Just after the war, the facility that had been most involved with the production of polonium, the Dayton Project (which became the Mound Laboratory), and Rochester continued with long-term studies, while the group at Chicago's Argonne National Laboratory completed a long-term study with mice.

Among the key findings with polonium are:

1. The route of administration can make a very large difference in the tissue distribution. This can be attributed to the relative importance of radiocolloids by the several routes of entry.
2. Toxicity varies less with route of administration than does the tissue distribution.
3. A variety of tumors of soft tissue can be induced by polonium.
4. A unique cardiovascular lesion is produced in certain narrow dosage ranges. It consists of thickening of arteriolar walls, obstruction of circulation,

ischemia, and necrosis. When this occurs in the kidney, a typical nephrotoxic syndrome can develop, including hypertension.

5. At high to moderate doses, polonium is more effective biologically than the long-lived bone seekers. However, at long times, it is about equal to radium in broad terms.
6. Results from tracer studies with five hospitalized patients at Rochester indicated distribution and excretion similar to that worked out in the animal experiments.

In more recent years, there has been considerable interest in the possible role of polonium that gathers naturally on tobacco leaves in the etiology of lung cancer in cigarette smokers. This has not been settled definitively.

There are significant amounts of naturally occurring polonium in the environment. Work done in the marine environment indicates the presence of very high concentrations in certain sea plants and fish viscera.

The pressure for further biomedical work with polonium has eased. It is no longer manufactured in quantity for the military, and better sources have been worked out for static eliminators. It is the possible role in the effects of tobacco smoke or inhaled radon daughter products that keeps interest in this element alive, plus its usefulness as a tool to study alpha-particle effects.

B. Thorium

The biomedical as well as the physical and chemical stories with thorium, and the members of its decay series, are far more complex than those with polonium. Thorium isomers are still used in industry, and the long-term effects of Thorotrast in man are still being worked out. The complex decay chain has made work with the thorium series much more difficult than work with most of the other radionuclides discussed in this book. We have, indeed, seen the dilemma of having one set of experiments that seemed to prove that thorium was all but inert toxicologically, and others that place it close to plutonium in relative toxicity. It all depends on which isomer is being dealt with and at which point in the decay series one enters.

Animal work involving thorium has been rather diffuse. Rochester, NYU, and the University of Utah have been the principal contributors in the United States.

The broadest effort has gone into study of the Thorotrast cases. Many thousands of individuals, especially in Europe, received this radiopaque medium before its propensity to remain in situ indefinitely and eventually to produce cancer in soft tissues was realized. Several discrete populations have been under study: three are in Europe (Denmark, Portugal, and West Germany), one is in Japan, and there are less homogeneous groups in the United States. It was thought that these would provide epidemiologic data comparable to the radium story. They have not, at least not yet. Dosimetry is very difficult, a possible factor of potential chemical toxicity is only now approaching resolution, and more time is obviously needed to get complete information on the pertinent populations. We can expect this to occupy future endeavors.

Some animal work on Thorotrast was done at NYU, Rochester, and Utah, but this too, requires extension.

On the whole, many dilemmas persist with thorium. If a thorium fuel cycle should receive serious attention, we can expect a resurgence of work in the field. If not, we can hope for continuation of the Thorotrast studies to their logical conclusion, but not very much more.

Preface to Section II

The Manmade Radioisotopes

The four chapters in this section involve the most active period in nuclear science; in some respects the most active period in all of scientific history. It goes from the first small-scale demonstrations of transmutation of the elements by radiations from naturally occurring radionuclides; through the production of radioisotopes by various accelerators, such as the cyclotron; the discovery and applications of nuclear fission with the production of thousands of new radioisotopes; the production of plutonium and other transuranic elements; the atomic bomb and the widespread applications of nuclear energy in the affairs of man. These events have been chronicled in depth elsewhere. A few of the key nonbiological events will be set down in these chapters largely for orientation purposes. The primary focus will be, of course, on biomedical aspects.

In contrast to the rather plodding pace of work with naturally occurring radionuclides during the earlier decades of the twentieth century, the work on manmade isotopes developed with amazing rapidity. Part of this was, of course, the stimulus of World War II, but the pace in the 1930s was also rapid. Sheer enthusiasm for what could be done with the new high-energy accelerators created the environment for rapid development of new techniques, new fields, and new applications. This included biology and medicine.

To a degree, all the remainder of this book considers manmade isotopes more than those that occur naturally. Yet we have already seen that the naturally occurring radionuclides are still of interest and importance. Thus, later sections will sometimes involve both manmade and natural radionuclides as is convenient to the subject at hand.

In contrast to the depictions of the series of naturally occurring radionuclides in the preface to the previous section, we reserve discussion of the major categories of these new isotopes for the individual chapters. Such discussions need to be close to the discussions of biology. In chapter 6, the general characteristics of the fission products and their production are described briefly. In chapter 7, we trace the remarkable progression in development of the actinides—so-called by Seaborg because they were considered to be chemically related to actinium—from an unweighable invisible source of activity to kilograms, even tons, and how the biomedical community kept up with these rapid-fire developments.

The decade of the 1930s saw the new accelerators pressed into service for production of radioisotopes for many purposes. Included was their use as

tracers for biochemical reactions, for physiological functions and the beginnings of nuclear medicine. It was an exciting decade for "basic" research. There was unusually close liaison, indeed collaboration, between the physicists and the biologists and physicians. Chapter 5 gives a brief review of the developments most pertinent to our mission and of the flavor of the 1930s.

The period of World War II is reviewed under two headings "New Dimension Number One—the Fission Products" and "New Dimension Number Two—The Actinides and Transuranium Elements." This was a period of frenetic activity for the biomedical community as much as for the physicists, chemists, and engineers. No one knew whether or not the Germans had made headway with the development of atomic weapons. There was much suspicion that they might have since the basic phenomena of nuclear fission had been discovered and described in Germany. The haste to "beat the Nazis to it" that motivated what became the Manhattan Engineer District (MED) was felt just as keenly by those who wanted to know something about the biomedical properties and effects of the new families of radionuclides expected to be produced. The progression, while not as dramatic as the development of the first chain-reacting "pile," etc., was full of new vistas that took not only the war years but several postwar decades to follow through on. Chapters 6 and 7 consider this era with special emphasis on reporting some of the wartime work that did not get published (see general preface and Appendix C).

The conditions of work during the years of World War II were far from luxurious. Seaborg's diagrams and pictures of the floor plans of his laboratories in the Metallurgical Laboratory buildings at Chicago show space allotted to senior chemists with enormous responsibilities that a present day undergraduate would find cramped (Seaborg 1977).^(a) Furthermore, salaries were uniform and no more than adequate. Research associates (senior investigators with Ph.D. degrees and considerable experience) might get as much as \$350 per month, a fresh Ph.D. \$250 per month, a research assistant \$225 per month, a B.S. degree chemist with experience \$150 per month, etc. Faculty members from universities were offered a 20% boost over their current salary and a small cost-of-living allowance (Seaborg 1977). They worked a full six-day week, including Thanksgiving, and many an entry in the Seaborg papers shows meetings and experiments on Sunday. It is true that expenses were low too. Seaborg notes his round-trip train fare to Buffalo from Chicago for a meeting at under \$40 with Pullman accommodations. He notes a round-trip to Urbana for about \$9, and his hotel there cost \$2.25. Thus the salaries went further than you would think.

Under these conditions, the workers could devote every working moment to the task at hand, but there were few luxuries. Nor should there have been. The alternatives were trench or naval warfare, even losing the war. All those with scientific training wanted to use it in the service of their country. Compartmentalization and security measures resulted in only a few key individuals in each group knowing the ultimate purpose of the work. The new elements and compounds had code names, and the biologists theoretically did not know what they were studying. However, surmises could be drawn and were, simply from the nature of the effects seen and the metabolic behavior of the compounds studied. Such surmises were kept to oneself in the MED days.

(a) I am most grateful to Dr. Seaborg for providing me with a copy of this four-volume scientific and anecdotal history of the chemistry section (C-1) of the Metallurgical Laboratory.

Only a relatively fleeting glimpse of all this could be fitted into chapters 6 and 7. Yet it is hoped that they provide guidelines to the major accomplishments (along with those on uranium reviewed in chapters 2 and 9) and entree into the pertinent literature for desired follow-up.

Chapter 8 continues the main threads of the wartime laboratory research on biomedical aspects of the radionuclides, particularly their toxicology, into the postwar decades. It is by far the longest and most detailed chapter in this section. While the MED efforts in biomedicine were concentrated and all-consuming for those involved, the total manpower was not large in comparison to that brought to bear in the postwar years. Also, the effects considered during the war were largely acute effects with only the continuing reminder from the radium cases that long-term chronic effects were lurking in the shadows. The postwar years saw a large expansion of total manpower and budget in order to attack the long-term problems. The experiments became much longer, the ramifications from the war work required far larger staffs, and further new dimensions intruded. I have termed it a "Golden Era" for internal emitter research because there were few constraints except our ignorance of basic mechanisms. It is only partly described in chapter 8. The enormous efforts in inhalation toxicology of radionuclides are considered separately (chapters 9 and 10), and an entire section of five chapters is devoted to the environmental aspects. Thus, this section considers only the laboratory research with manmade radionuclides of the war years and a portion of the laboratory research in the postwar decades.

Chapter 8 includes a fairly detailed description and chronology of the development of the several long-term experiments with radioisotopes developed to approach the long-term effects of relatively low levels of exposure. These were difficult, expensive, and almost unique. Only the efforts with external radiation sources, and the huge genetic experiments with mice at Oak Ridge were comparable. These experiments will never be done again. Therefore, even though the final conclusions are yet to come,^(a) much space is devoted to providing a reasonably comprehensive record of the underlying motivations, the organizations and modus operandi, and the results of these experiments.

It is to be hoped that the region of comparable long-term low-dose effects of chemical toxins in the workplace and in the environment (until recently an area sadly neglected) can benefit from the lessons learned in these large efforts with radionuclides. The longer a concentrated attack on the chemical problems is postponed, the greater are the chances for irreversible damage—a prospect that seems relatively remote in the radionuclide field, barring a nuclear catastrophe. The patience and dedication of hundreds of biomedical scientists should show through in these chapters, along with the wisdom and tolerance of the supporting agencies. This includes the United States Congress, especially the unique Joint Committee on Atomic Energy, and the Division of Biology and Medicine of the Atomic Energy Commission and its successor agencies.

1. The first part of the document discusses the importance of maintaining accurate records of all transactions. It emphasizes that proper record-keeping is essential for the integrity of the financial system and for the ability to detect and prevent fraud.

2. The second part of the document outlines the specific procedures for recording transactions. It details the steps involved in the accounting cycle, from identifying the transaction to posting it to the appropriate ledger account.

3. The third part of the document discusses the importance of internal controls. It explains how internal controls can be designed to prevent errors and fraud, and how they can be used to ensure the accuracy of the financial statements.

4. The fourth part of the document discusses the importance of auditing. It explains the role of the auditor in verifying the accuracy of the financial statements and in detecting any errors or fraud.

5. The fifth part of the document discusses the importance of the Sarbanes-Oxley Act. It explains how this act has changed the way that companies report their financial information and how it has increased the accountability of corporate executives.

6. The sixth part of the document discusses the importance of the Generally Accepted Accounting Principles (GAAP). It explains how these principles provide a common framework for the preparation of financial statements and how they are used by investors and other stakeholders to make decisions.

Capsule Chronology^(a)

- 1919** First artificial transformation of an element; alpha particle on nitrogen (Rutherford).
- 1930–1932** Invention of cyclotron (E. O. Lawrence and M. S. Livingston at Berkeley). Plans outlined in 1930. Paper sent to press in 1931, published in 1932.
- 1931** Van de Graaff electrostatic generator constructed.
Linear accelerator constructed (Sloan and Lawrence at Berkeley).
- 1934** First artificially produced radionuclide (Irène Curie and J. F. Joliot, Paris).
Realization that cyclotron at Berkeley could be used for production of radioisotopes useful for tracer chemistry and biomedicine (Henderson, Livingston, and E. O. Lawrence).
Production and use of radiosodium. Prophetic to nuclear medicine (Hamilton and Stone at Berkeley).
- 1934–1946** Cyclotron and other accelerators produce hundreds of radionuclides of use in biology and medicine.
- 1935** Hevesy publishes on uses of radioisotopes in biology (Copenhagen).
Lawrence uses ^{24}Na as a tracer (Berkeley).
- 1936** First use of ^{32}P in therapy (John Lawrence, Berkeley). Produced in 37-in. cyclotron. Also prophetic to nuclear medicine.
- 1936–1940** Use of radioiodine from MIT^(b) cyclotron. Patients at MGH (Evans et al.). Animals at MIT (Hertz, Roberts, and Evans).
Tracers demonstrate the dynamic state of body constituents.
- 1937 et seq.** Radioiodine used for diagnosis and therapy (Hamilton and E. O. Lawrence at Berkeley).
Use of radiosodium in humans grows.
- 1937–1939** Seaborg and colleagues produce and isolate many radionuclides of importance to biology and medicine using Berkeley cyclotrons, mostly the 37-in. machine.
- 1938** Radioiron revolutionizes ideas about iron metabolism (Hahn, Bale, Lawrence, and Whipple at Rochester).
Rochester cyclotron produces many other isotopes for biomedical use.
Electron-capture radionuclides discovered (Alvarez at Berkeley). Much use in biomedicine because of low dose delivered.
- 1938 et seq.** All physics work at Berkeley's 37-in. cyclotron suspended for one full day each week to allow treatment of cancer patients with neutrons.

(a) This considers primarily the decade from 1932 to 1941.

(b) For abbreviations and acronyms, see Appendix D.

1939 The 60-in. cyclotron at Crocker Laboratory, Berkeley, goes into operation and is designated a "medical cyclotron."

Kamen and colleagues use ^{11}C extensively in biochemistry.

1940 Kamen produces and uses ^{14}C .

1941-1946 Phosphorus-32 and other radionuclides obtained from a growing number of accelerators (Ohio State; Washington U., St. Louis; etc.).

Chapter 5

The Early Days of Manmade Radioisotopes

Overview

This short chapter provides a bridge between the first major section of the book, "The Naturally Occurring Radioisotopes," and the second, "Manmade Radioisotopes." It provides a brief summary of the first years of manmade radioisotopes and their significance to biomedical science. While nominally it concentrates on the decade of the 1930s, which includes some years prior to the announcement of the first artificial production of a radioisotope in 1934, it also reaches back into the 1920s when the first tracer experiments were done. It includes a few events that came to fruition in the 1940s.

The discussion is aimed primarily at establishing the setting in which the intensive researches on the biomedical behavior of radioisotopes were carried out during World War II. The era marked fundamental changes in our concepts of life processes. Only relatively broad concepts are described. The literature citations are sparse and consist mostly of citations of unusual historical importance or illustrations of points under discussion. A few general references are given to pertinent monographs and texts. Most of these were written in later years, but they include substantial summaries of the period of interest.

The final section takes up the bearing of the work of this era on our primary focus. Actually, there was little formal work on the toxicology of the new manmade radioisotopes except as an adjunct to isotope therapy. Nevertheless, essential techniques and instrumentation were developed and some preliminary ideas formulated that were essential to the more overt biomedical investigations in later decades. These are considered briefly.

There are also a few speculations on the possible presence of untoward effects in man during these years of rapid development of a new and initially esoteric tool.

I. Introduction

With this chapter, we begin the subject that will occupy our attention through most of the balance of this book: the behavior and effects of manmade radioisotopes in living organisms. By the "early days" we mean primarily the decade

of the 1930s. This was a remarkable decade in nuclear physics and marked the final transition from classical to modern eras. Included was, of course, the development of several kinds of high-voltage machines for accelerating particles to impinge upon a target. Of special importance to biomedical science was the invention of the cyclotron (Lawrence and Livingston 1932).

The field of tracer chemistry, i.e., the use of tagged atoms as tracers for the behavior of a stable element or as a marker for biochemical reactions, came into its own during this decade. Also, nuclear medicine, which is a direct descendant of tracer chemistry, began, although not with that name. By the end of the 1930s, a relatively rare technique and something of a curiosity had become a commonplace tool in much of biomedicine. The changes in biomedical science were indeed almost as dramatic as those in nuclear physics, albeit accompanied by less fanfare.

A book devoted to milestones in understanding the health effects of radioisotopes cannot neglect discussing this era, even though the concerns for effects were not nearly as strong as in following decades. Since ample reviews of the details of this era are legion, the coverage here will be primarily for historical perspective. Only a few direct literature citations will be made, since, on the whole, this is not the place to discuss the research results. There is a general bibliography at the end of the chapter, which gives some of the key monographs and texts pertinent to the era.

II. Preparing the Way

The method of radioactive indicators began well before manmade radioisotopes were available. The idea that isotopes could exist was accepted in the early 1900s. Rutherford observed in 1919 that bombardment of the nitrogen atom by alpha particles from natural sources resulted in production of an isotope of oxygen.^(a) Hevesy and Paneth collaboratively used radium-D^(b) (^{210}Pb) as a tracer for the behavior of a stable element, lead, in inorganic reactions as early as 1913 (Paneth and Hevesy 1913; Hevesy and Paneth 1938). Hevesy entered the biomedical field with a study of the absorption and translocation of lead by plants, viz., bean roots (Hevesy 1923). In both cases, it was a most ingenious conversion of failure in one enterprise (separating radium-D from "all that nuisance lead," impossible because radium-D was an isotope of lead) into glowing success in another (the tracing of a stable element by one of its radioactive isotopes). Very soon, Hevesy published (with collaborators) the first experiments on animals. These used radium-E, which is a 5.0-day-half-life isotope of bismuth (^{210}Bi). Lead-210 (thorium-B), already used in the bean root experiments, was also tried in animals.

Many other tracer experiments followed as described in detail in the informative two-volume collection of Hevesy's papers (Hevesy 1962) and in the many tracer chemistry compendia listed at the end of this chapter.

(a) It became clear that the old dreams of the alchemists to transform "base metals into gold" had been unrealized because a nuclear reaction is required. Only when the strong electrostatic repulsion of the charged nuclei in atoms is overcome can nuclear reactions occur. This requires the high initial velocity seen only with high-energy ionizing radiations, and these do not occur in ordinary chemical reactions.

(b) For convenience in reading the early literature, the now obsolete terminology (radium-D, etc.) is used temporarily.

At Harvard, Herman L. Blumgart and colleagues used solutions of radium-C (^{214}Bi) in the late 1920s for injection into humans (Blumgart and Yens 1927; Blumgart and Weiss 1927). Their aim was to study the velocity of the circulation, which they did by injecting the ^{214}Bi solutions into one arm and detecting the appearance of the energetic gamma rays in the other. Their detection device was nothing other than a modified Wilson Cloud Chamber placed on the un-injected arm. (It was later replaced by an early type of Geiger counter.) The usual arm-to-arm circulation time was eighteen seconds. This general method using naturally occurring gamma-emitting isotopes was expanded to measurements of pulmonary circulation time, blood volume, and many other physiological processes. (More in chapter 20.)

There were a few tracer experiments done using ^{226}Ra and ^{222}Rn . This latter was also pioneered by Blumgart and, according to Shields Warren (Warren 1978), may have preceded the use of radium-C and thus been the very first use of an isotopic tracer for a physiological measurement in man. But the detection of alpha particles posed much greater problems than the gamma rays from substances like ^{214}Bi . Fortunately, relatively few such experiments were carried out in humans. From what we now know, such use of alpha-particle emitters would have been hazardous.

These works established the basic methodology of tracer chemistry for use both in vivo and in chemical systems in vitro.

In the early 1930s, Urey separated deuterium from hydrogen. This had two especially important results. The use of stable isomers as tracers for their more abundant companions began in earnest. Later, the nucleus of deuterium was to become a most useful projectile for accelerators. The mass spectrograph assumed an important role as another tool for the method of tracer chemistry, and some important findings regarding the dynamic state of body constituents resulted.

III. Manmade Radioisotopes Enter the Picture

The first production of a new radioisotope by the deliberate transmutation of another element through the ingenuity of man is attributed to Irène Curie and her husband Jean Frédéric Joliot.^(a) They had been bombarding various light metals with alpha particles from ^{210}Po . Emission of neutrons, protons, and positrons ($+1e$) resulted from such bombardment. The key observation was that, while the neutron and proton emissions ceased, the positron emission *did not* cease after cessation of the bombardment. It continued with an activity that decayed away exponentially with time as for an *ordinary radioelement*. The phenomenon was seen with several light metals. The products were all new radioelements, and they had been formed *de novo* in the experiment. In the case of boron, the result was ^{13}N . In the case of aluminum, the result was ^{30}P . With magnesium, the product was ^{27}Si .

Having already seen the ease with which credit for a new discovery can travel away from its rightful recipient, Irène and her husband got off a quick note to *Nature*, which was published in the February 10, 1934, issue (Joliot and Curie 1934). The first production of a new radioisotope by man had been

(a) The reader will remember that we forgave the delay caused by Irène's gestational period in her mother's isolation of radium because she was later to do something big in her own right (cf chapter 1).

accomplished, a process markedly in contrast to the separation of constituent elements from naturally occurring mixtures.

Within a month of the Joliot-Curie announcement, the Berkeley group announced the use of both deuterons and protons in the cyclotron to bombard a variety of elements between lithium and chlorine. Every target was observed to emit both gamma radiation and ionizing particles (positrons) for some time after bombardment ceased. The activity fell off exponentially with time and was characteristic for each target element. The paper was done by Henderson, Livingston, and Ernest Lawrence and appeared in the *Physical Review* for March 15, 1934.^(a)

In this case, the source of the bombarding particles was a machine invented and made by man. Its capacity to produce new radioisotopes exceeded by far that of even the most powerful source of natural alpha particles. The age of artificial radioisotopes was under way in earnest. Tracer chemistry rapidly took over much of biochemistry, some of physiology (e.g., Hamilton and Stone 1937), and bits and pieces of medicine.

Developments succeeded each other in close succession. Radioisotopes of the physiologically important elements such as sodium, potassium, chlorine, bromine, iron, phosphorus, and iodine were given to both humans and animals. A popular technique in man was to place one hand within a box with a thick lead shield and grasp a counter tube. This tube could register the appearance of these entities as a function of time after entrance to the body via the digestive tract. It became clear that sodium was much more mobile than potassium and that potassium was largely bottled up inside cells. Excretion of the radioelements was determined both in the normal human and in patients with various diseases.

Especially useful and popular isotopes in this era were ^{24}Na ; ^{42}K ; ^{128}I , followed in time by ^{130}I , and later still ^{131}I (^{125}I did not enter until 1946); ^{32}P ; several isotopes of sulfur, the most useful being ^{35}S , which is now produced in a nuclear reactor; isotopes of chlorine; and several isotopes of iron, primarily ^{59}Fe and ^{55}Fe . Most of the tracer work involving reactions of hydrogen involved heavy hydrogen (deuterium), since the existence of tritium, the radioactive isotope, was not demonstrated until 1939.

Experiments in the tracer realm with these demonstrated strikingly what Hevesy called in his Nobel Prize lecture "the dynamic state of body constituents," i.e., the molecules building the organism are incessantly renewed. Perhaps most surprising was the rate of turnover of atoms and molecules in bone, formerly considered a more or less static structure. Also, the work with isotopes of iron completely revolutionized ideas concerning iron metabolism and its role in the body economy (Hahn et al. 1938). This included both the realization that iron in certain vital molecules is jealously guarded against deficiency of intake and that iron is absorbed from the gastrointestinal tract only as it is needed to maintain the stores at optimum levels.

With the addition of radiocarbon to the roster of radioisotopes (first the short-lived ^{11}C and later the long-lived ^{14}C) by Kamen, entrée was obtained to both the bicarbonate- CO_2 cycle and the vast domain of organic compounds in biochemical reactions. Classic experiments using radiocarbon, such as the early

(a) Without doubt, the phenomenon had been occurring all along in accelerator targets, but the after-decay was not focused upon until the Joliot-Curie announcement drew the attention of the Berkeley workers.

ones at Harvard on glycogen synthesis and the work on photosynthesis at Berkeley, brought about radical revisions concerning our ideas of the mobility, transfer, and synthesis of carbon compounds of biochemical importance.

The cyclotrons at Berkeley were unabashedly devoted to biomedical work. This was in part because Ernest Lawrence had always had an interest in medicine, and his brother John, a physician, was close by to help with biomedical details and the selection of important problems to study. Such collaboration was not limited to Berkeley, however. There were cyclotrons at Harvard-Massachusetts Institute of Technology (MIT), Rochester, and Washington University, all devoted to a significant extent to the preparation of radioisotopes for biomedical work. In fact, for nearly all, the base for supporting funds was partly the promise of their products to biological and medical research and therapy.

One of the most completely developed histories of the role of collaborative efforts of workers from many disciplines is seen in the organization and construction of the joint MIT-Harvard cyclotron as described by Robley Evans in a review published much later (Evans 1975; also Brucer 1978). The *raison d'être* was entirely medical, and the first (by a short time) administration of radioiodine (the short-lived ^{128}I) to a patient came as a result of this effort. Soon, radioiodine was being used in several places. Among these was Berkeley, where Joseph Hamilton, a young physician (originally a psychiatrist but also a first-class chemist), worked under the stimulation of both John and Ernest Lawrence. We will have many occasions to consider other aspects of Hamilton's work in later contexts.

Tracer chemistry was not the only goal in these works. Besides the obvious physical experiments, the Lawrence brothers, for example, had therapeutic uses as a primary objective in building their machines. Indeed the largest cyclotron of the decade, the 60-in. machine at the Crocker Laboratory, was called "The Medical Cyclotron" (Lawrence 1939).

Therapeutic amounts of several radioelements were indeed made and used, some of them before (and during) World War II (Evans 1975; Brucer 1978). Radiosodium (^{24}Na) was tried at Berkeley to deliver the equivalent of whole-body external radiation in the treatment of leukemia. Radiophosphorus (^{32}P) was applied in several centers both in the United States and abroad (especially in Hevesy's laboratory) for the treatment of blood disorders. The first therapeutic use of ^{32}P appears to have been by John Lawrence on Christmas Eve of 1936. Phosphorus-32 eventually became the treatment of choice for polycythemia vera, and hopes were high for its effectiveness in the treatment of some forms of leukemia. (More about this will appear in the chapter on nuclear medicine.)

To bring about these accomplishments, much individual labor and experimental insight were needed. A decent tracer experiment or preparation of an isotope for therapeutic administration required team efforts and group spirit. Many of the early isotopes of greatest interest had relatively short half-lives. Progression from removal of the target to final counting had to be accomplished with dispatch. Organization of the many steps resembled a military operation. Chemical separations were necessarily by the classic methods. (Ion exchange methods had not yet come on the scene.) The early steps required considerable shielding against radiation and help from the cyclotron crew. The later steps required decisions on whether to measure the activity of the product in a solid or gaseous form and in what chemical compound. Nearly all variations were tried. While the tedious final counting beat endless titrations, many technicians had to be consigned to long days of work at the manually operated and

somewhat temperamental devices for counting radioactivity. Comparison to standards had to be rigorous and frequent.

There were pitfalls too. Rigorous criteria of isotopic purity were required. One had to be certain that the tracers were not wandering from one moiety to another without the knowledge of the experimenter. With the very small amounts involved, the chance that the tracer was attached to an impurity rather than the substance under study had to be guarded against. The phenomena of low concentration chemistry were, of course, inevitably involved, while, especially at higher concentrations, the production of radiocolloids had to be reckoned with. Many practical solutions were put together from necessity; and these persisted into other areas such as radioisotope toxicology. As Martin Kamen warned, bad chemistry is still bad chemistry, even with the convenience of a handy tracer atom. Perhaps it was even more likely to occur because the low concentrations precluded some of the classic tests of purity. But on the whole, the active participation of physical scientists in the teams made the errors less numerous than they otherwise might have been.

A further example of fruitful collaboration among physics, chemistry, and medicine is seen in the genesis of more or less pure ^{131}I . The short half-life of ^{128}I (twenty-five minutes) was a nuisance for both producer and user. The anecdote concerning its isolation^(a) has appeared in several places. We will quote the text used by Brucer (1978). The principals are Joseph Hamilton and Glenn Seaborg at Berkeley in 1938.

Unaware that a 13-day iodine had been announced in February, one day in the spring of 1938 Hamilton ran into Glenn Seaborg on the steps of Le Conte Hall (the physics building at Berkeley). Seaborg was the chemist who prepared the pure radioisotopes from irradiated cyclotron targets. Hamilton complained bitterly about the 25-minute half-life of I-128; "Why can't you make me an iodine isotope with a longer half-life?"

"We can," said Seaborg. "How long a half-life do you want?"

"Oh, about a week."

Seaborg and his physicist partner, Jack Livingood, prepared some tellurium targets. They bombarded the targets in the 37-inch cyclotron with 8-MeV deuterons. Chemical separation and identification procedures were carried out while wearing gas masks to ward off the dreaded "tellurium breath." In a week Seaborg delivered the first and only radioisotope ever discovered to fill a physician's prescription, a sample of a new 8-day iodine-131 with the comment, "If you don't like what we're making we'll discover something else."

Brucer comments further:

I-131 was a significant achievement, not because it later became top-dog in Nuclear Medicine, but because it opened up the possibility that alternate choices of nuclides possibly meant a choice of dosages—maybe even therapy could be considered. (Brucer, 1978)

The publication reported both a twelve-hour ^{130}I and the eight-day ^{131}I (Livingood and Seaborg, 1938).

There was tedium also in the cyclotron operations. Irradiation times sometimes had to be quite long, especially to prepare the quantities of isotope needed for therapeutic trials. Physicists whose main research interests were in

(a) The possibility of longer-lived iodines was recognized in the mixtures in 1937 by letting them "age" and the ^{128}I , for example, decay out.

other directions developed almost saintly patience during these long sessions, based in general on their personal conviction of the importance of the biomedical work. One of these was Arthur Roberts, a member of the MIT-Harvard team that first reported the uptake of radioiodine as a measure of thyroid function in rabbits (Hertz, Roberts, and Evans 1938). At a much later time, probably the fall of 1942 (Evans 1981), Roberts produced a somewhat wistful ditty around the long hours of cyclotron irradiation times entitled, "The Cyclotronist's Nightmare or Eight Millicuries by Half-Past Nine." The first verse reads:

Once upon a midnight dreary
The cyclotron crew was weak and weary;
In walked the Boss with a smile so cheery,
In walked the Boss with a very broad smile.
"Boys" he said, "Here's a wonderful chance"
"Boys" he said, "It'll make you want to dance"
"Boys" he said, "We must activate some iron"
"Eighty millicuries by half-past nine."^(a)

We will have reason to return to this text in another connection in section IV.

There is no doubt that these new methodologies added an entirely new dimension to biology and medicine. In addition to the research findings themselves, the close collaboration of scientists from many disciplines was an essential ingredient. In retrospect, it was in basic biochemistry and physiology that the quantum jumps were made. Therapy was intriguing and stirred much enthusiasm but was not so obviously a new dimension.

The meaning of the 1930-1940 development of tracer chemistry and the preludes to nuclear medicine to our subject of possible health effects is not as direct as in later years. But it was very real, as we shall see in the next section.

IV. Overtones for Radiation Toxicology

During the decade of the 1930s, excitement ran very high for exploring the new vistas opened by the availability of radioisotopes. Possible untoward effects of these new entities were undoubtedly frequently either not considered at all or brushed aside as minimal.^(b) The painful saga of the radium dial painters, chemists, and patients was slow to cross the boundaries into conventional physiology, biochemistry, and medicine, which were undergoing a quiet revolution, as the tracers demolished one old idea after another. Quite obviously, the highly radioactive targets, i.e., the source material, required considerable shielding and special techniques. The early radiation protection experts were quite aware of the potential hazards of radioisotopes in the body, as well as their potential as sources of external radiation, and let their thoughts be known. But once the "hot" sources were diluted to tracer levels, worries over toxic effects were minimal. On the whole, this sanguine attitude was probably justified for tracer applications.

(a) Excerpted from copy kindly supplied by Robley D. Evans (1981) who was "The Boss" in this not so fictitious composition.

(b) By contrast, there was immediate and substantial interest in possible toxicity of heavy hydrogen (deuterium) as soon as it was separated in quantity. Indeed, some effects were found.

1. The amounts of radioisotope used were necessarily small because the amounts available from the accelerators were small in an absolute sense.
2. The half-lives of the more commonly used materials were relatively short.
3. The investigators were sufficiently aware of the biological effects of radiation to make every effort to be sure the radiation doses from the tracers did not alter the processes under study.
4. The equipment of even this early decade was sufficiently sensitive to respond to very small quantities of radioactive materials. Contamination of laboratory and equipment had to be scrupulously avoided. Thus, the needs of the experiments brought with them a considerable measure of safety.

There had to be some careless workers and some laboratories where potential health hazards were pooh-poohed. Fortunately, the nature of the isotopes and the small quantities involved made it unlikely that tracer-chemistry experiments per se were responsible for demonstrable health effects. It was the personnel manning the accelerators who were vulnerable and who died later of leukemia or developed cataracts from the practice of lining up the cyclotron beam by eye. We cannot be sure, but it seems likely that external radiation from the beam and scatter played a more important rôle in these deaths than radioisotope ingestion or inhalation.

The situation was somewhat different in the realm of planned therapeutic administration to humans. The dial-painter story had alerted some segments of the medical profession and, even then, a vocal segment of the public and the press. John Lawrence tells in an after-dinner address given at the second annual meeting of the then-new Society of Nuclear Medicine (Lawrence 1956, extracted and published in 1979 in the *Journal of Nuclear Medicine*) of the suspicion directed toward those members of the medical profession who gave demonstrations on the creamed-chicken circuit by swallowing a small amount of radioiodine or radiosodium, or did a tracer experiment with an animal or plant. The idea that application of artificial radioactivity to humans would amplify alarmingly the tragedies seen in the dial painters was raised clangorously in some quarters. The large difference in biological effectiveness of the beta and beta-gamma emitters compared to alpha emitters like radium, the effect of the much shorter half-lives and deposition in general in soft tissue rather than bone were not grasped by those alleging that the radium saga was being extended to new, unsuspecting recipients.

On the other side of the coin, there is no doubt that some of the practices and some of the doses would not pass muster today. The investigators had a strong (and understandable) tendency to use themselves as guinea pigs for new isotopes and new ideas. Recommendations for permissible dose were more lenient than they are now. We cannot point to any specific instances of proven damage to investigators or patients from the use in humans of therapeutic doses of artificially produced radioisotopes in the 1930s. But neither can we be sure that there were none. The number of individuals involved was far too small to permit an acceptable retrospective epidemiologic study. Hence, we will probably never know the extent of the toxicological effects of therapeutic levels of radioisotopes used in that decade. It is unlikely that the number is zero.^(a)

(a) Clearly some of the early patients were alive and well in the 1950s, and a few remain today who would probably have died of their malady had they not been treated. Thus, even if there were risks there were also benefits.

The composition by Arthur Roberts quoted in the previous section has as a subtle theme in a later refrain the possible confusion of units; the prescription called for *milligrams* not *millicuries*. Here in jocular song and verse is one of the nightmares of dosimetry, the misread unit or the misplaced decimal point. That such mistakes have been made, albeit very infrequently, is part of the folklore of nuclear medicine, as of all of drug therapy. Deleterious effects no doubt resulted from these. But it is not our function here to attempt to document these rare instances, except to say that, in general, they were less likely to happen with the new radioisotopes than with conventional drugs. The low frequency of use in the decade of the 1930s would alone preclude there being many instances. Nevertheless, in reviewing the overtones for toxicology of the decade of the 1930s, we must note such possibilities.

A sidelight on considerations of toxicity in this period lies in a story told by John Lawrence at the Society of Nuclear Medicine meeting already cited. There was much interest in the biological effectiveness of the neutrons from the cyclotron. Paul Aebersold, whom we will meet in later chapters, was a graduate student at Berkeley at the time. He fashioned a small chamber that would hold a rat and that could be placed near one of the Dees within the cyclotron. The machine was turned on for *three minutes*. The crew then crawled into the space to retrieve the animal. The rat was dead. This caused considerable alarm and, according to Lawrence, instilled great respect for the biological potential of these new radiations. This respect lasted, and it undoubtedly prevented some rash and dangerous short cuts in cyclotron operations. It was not until twenty years later that Lawrence admitted that the histologic sections from that rat showed that it had died of suffocation (Lawrence 1956, 1979).

The uses of radioisotopes in these early years made many contributions to radioisotope toxicology as we now know it. These included:

1. development of instrumentation
2. development of methodologies for preparation and handling of radioisotopes
3. development of calculations for the estimation of dose from both the tracer and therapeutic levels, especially the latter
4. development of standards for worker exposure
5. characterization of the pharmacokinetics (i.e., the location and translocation) of the principal radioisotopes. (Of special importance was the uptake in the organ of interest relative to other tissues or the whole body.)
6. preliminary characterization of the effects of beta and beta-gamma emitters
7. synthesis of and behavior of a wide variety of compounds containing radioisotopes
8. effects of disease states on the behavior of radioactive elements alone or in specific compounds.

Let us consider a few of these in more detail.

The methodologies developed for preparing and handling radioisotopes for tracer experiments or for therapy were essentially the base line for the work of the following decade (chapter 6), except for alpha-emitter detection and measurement. Alpha emitters were already in the domain of radiation toxicology by virtue of the work with radium. Radiation doses were estimated rather crudely, primarily on the basis of energy and half-lives. The rad unit had not been proposed. The complex internal dosimetry of the next decade was still to come. But empirical determination of no-effect levels was engaged in frequently. In the

case of tracer chemistry, radiation effects could not be allowed to complicate the basic processes under study. For therapy, concentrations had to be effective to the target tissue without undue damage to normal tissues. By virtue of constant testing, the dose of ^{32}P , for example, which would be effective against polycythemia vera, yet would not produce unacceptable damage to other bone marrow cells, was worked out as best it could be. Individual variations in response and apparent sensitivity were large, however. As a result, questions of dose fell to some extent in the area of that sixth sense that therapists should have—clinical judgment.

Probably one of the most concrete legacies of this first decade of manmade radioisotopes to future work was in the characterization of the behavior of isotopes in the body. This was not overt. It was simply a coincidence in that the same kind of information was needed for both fields.

For reasons that are not entirely clear, radiation toxicology has made little use of the knowledge gained concerning the effects of disease states on the behavior of radioisotopes. Probably the focus has been so concentrated on toxic effects in normal organisms that the influence of pathological states has not been considered very important. Only in nuclear medicine do the possibilities of altered metabolism by virtue of the underlying disease state become a commonplace item to consider. Yet, as radiation protection extends beyond the normal worker, these considerations may become critical. Unfortunately, the literature on such influences, even for the first decade, is widely scattered and in need of review and compilation.

In toto, the interrelationships of the work in tracer chemistry during the first decade of manmade radioisotopes, the therapeutic uses, and our field of radiation effects are very loose and for the most part unplanned. The fact that both depend upon the same body of knowledge is their most tangible interrelation. The stage was being set for the intensive research to follow in and after World War II. We will consider these in chapters 6 and 7.

V. Summary and Commentary

There can be no doubt that the groundwork for tracer chemistry, nuclear medicine, and radionuclide toxicology was laid in the decades of the 1920s and 1930s. It started with the use of naturally occurring radionuclides as tracers; it received a considerable advance by the production of manmade radionuclides by Irène Curie and her husband, F. Joliot, in 1934; and a quantum jump made possible by the invention of various accelerators by the physicists. The cyclotrons at Berkeley were soon followed by machines at MIT, Washington University in St. Louis, the University of Rochester, and elsewhere. It was an era of close collaboration among physicists, chemists, and biomedical personnel. The short half-life of most of the radionuclides required real team work.

There was about an equal mix in the earlier periods of work aimed at biochemical and physiological mechanisms using tracers, applications to understanding of disease processes (especially the thyroid [^{131}I] and certain blood disorders [^{32}P]), and forays into frank therapy. Gradually, some separation of the lines of investigation began. It probably would have gone further, but the prodromal needs of the war effort interfered. Many of the principal investigators of the decades considered in this chapter became key individuals in the efforts to come in World War II.

Although our treatment is brief, it should be apparent that this period meant much for the future of all of biomedical science, both "pure" and "applied." If we compare the number of lives saved or made more comfortable by the products of these decades, as later applied, with the deleterious effects, even fatalities, occurring to date, we must conclude that these developments have had a positive impact overall.

Capsule Chronology

- 1939 Correct description of phenomena of nuclear fission (Meitner and Frisch, Germany).
- 1941 Pecher (Berkeley) finds that radiostrontium behaves like calcium and deposits in bone.
- 1942 The chain-reacting pile works. Large quantities of fission products expected.
- 1942-1943 Concern develops at Metallurgical Laboratory (Chicago) about potential hazards of radioxenon, and soon thereafter, of ^{131}I and fission products.
- 1942-1945 Concern over possible use of fission products in radiological warfare leads to Projects Peppermint and Gabriel.
- 1942-1947 Systematic study of fission products at Berkeley (Hamilton, Axelrod, Copp, Lanz, Scott, et al.). Radionuclides produced in 37-in. or 60-in. cyclotron. All work at tracer level because of small quantities. Parenteral, ingestion, and intratracheal routes of administration used.
- 1943-1945 Berkeley classified reports show tissue distribution, retention, and elimination kinetics.
- 1944 Substantial group begins work at Met Lab (Chicago) on biomedical aspects of fission products. Emphasis on effects, as well as metabolism. Some of the work done at Clinton Labs.
Special tools developed.
- 1945 Summary project reports from Berkeley. Each element seems to have its own behavior.
- 1945 et seq. Much work at Chicago (Schubert et al.) on radiocolloids and chemistry of fission products pertinent to biomedical problems.
- 1946 Barium-lanthanum couplet investigated in animals at Met Lab (R. Finkle and Snyder). Growth, development, hematological effects, LD_{50} .
- 1946 Fission products investigated as carcinogenic agents at Chicago (Lisco, M. Finkel, and Brues; also Prosser). Beginning of large experiment with mice. Carcinogenicity to bone demonstrated.
- 1947 Metabolism and effects of strontium investigated at Met Lab, Chicago (Anthony et al.).
Phosphorus-32 used for comparison and as base line for less well-known elements such as cerium.
Oral ^{91}Y produces carcinoma of the colon in rats (Grundhauser, Met Lab).
Transmission of fission products from mother to fetus studied at Chicago (M. Finkel). Included deposition in fetus.
Fission product studies with dogs using ^{89}Sr and ^{90}Sr begin at Chicago (Swift and Prosser). LD_{50} determined, as well as metabolism and hematology. First work with large animals.
Fission products studied in goldfish at Chicago (Prosser et al.).

Very complete reports from Berkeley on metabolism of strontium, barium, yttrium, cerium, praseodymium, zirconium, ruthenium, tellurium, iodine, xenon, cesium, and "fission product mixture." In general, gut absorption poor. Liver takes up considerable amounts early, but they soon leave and are either excreted or go to bone. Bone retention is quite long. Ruthenium, tellurium, cesium, and xenon do not localize in bone. Autoradiography shows considerable differences in microscopic distribution of different fission products in bone. Strontium is most like calcium.

1949 Open literature reviews of Berkeley work.

Ion distribution studied in plants (Jacobson and Overstreet at Berkeley).

Part of the Met Lab work reaches open literature, but much remains unpublished.

EARLY POSTWAR YEARS

Berkeley: Old 37-in. cyclotron disappears along with its building (the old "Radiation Laboratory"). Crocker Laboratory dismantled but 60-in. cyclotron goes (in pieces) to the University of California, Davis. Much activity in teaching about the new science of radioactivity.

Chicago: Large experiment continues on long-term effects and relative toxicities in mice.

Hanford: Biology work begins; includes iodine in sheep.

Chapter 6

New Dimension Number One— The Fission Products; 1939–1950

Overview

This chapter concentrates on what the biomedical community did to react to the enormous increase in potential levels of radioactivity and to the variety of radionuclides associated with the fission process. It is, thus, primarily a saga of research done under the pressures of World War II. Only to indicate the settings for the work and some extensions into the postwar years, which are essentially part of a continuum, does it stray from the 1940 to 1947 era. As a result, much work done earlier on isotopes of elements such as iodine, phosphorus, sodium, potassium, etc., is omitted here. These were reviewed when we examined the accelerator-produced isotopes of the early and middle thirties in chapter 5. Some, for example iodine, will come back in our consideration of postwar research (chapter 8) and of nuclear medicine (chapter 20). Others, like xenon, krypton, etc., which are primarily an inhalation problem, are deferred to the special chapters on this subject (chapters 9 and 10). This is done despite the fact that some of these radioisotopes are indeed fission products. The new information on the properties of the two hundred or so new radioactive isomers developed in nuclear fission and its pertinence to biology and medicine and to protection standards are the main business of this chapter.

I. The Problem

Plans for protection of the personnel of the Plutonium Project against the enormous quantities of radiation and radioactive materials expected to be produced began even before it was certain that the chain-reacting pile would work. After December 1942, when the pile did work, the problem was fully upon them (and all of us).

The products of uranium fission include, besides the energy released as prompt radiation and recoil, over two hundred isotopes of thirty-four elements extending from zinc to europium. About sixty nuclides occur as primary reaction products. The rest develop through chains of radioactive decay of these primary products.

Many authors have already pointed out, but it is still pertinent to relate again, the scaling factor introduced by the facts of nuclear fission. In the nearly half-century since its discovery to the early 1940s, about one kilogram of radium (i.e., one kilocurie) had been extracted worldwide from its ores. Yet, as we saw dramatically in chapter 1, this amount had presented serious problems of toxicity to hundreds of individuals. The chain-reacting piles of the Plutonium Project would produce hundreds of megacuries, a scaling factor from radium of at least 10^6 , and this was only for the first phase of the effort.

Further, as Hamilton (1949) pointed out in one of the first publications on the work of the Plutonium Project, only one of these radionuclides, iodine, had been studied in enough detail prior to 1942 to allow a reasonable evaluation of permissible exposures. Radiostrontium had also been studied but not sufficiently to meet the needs of the Plutonium Project. All of the others required evaluation of metabolic properties and eventually of effects. Some could be gauged by analogy to other elements. But by and large the investigators were in virgin territory regarding the behavior and biomedical significance of about two hundred essentially new substances.^(a) Finally, decisions needed to be made in great haste to avoid possible catastrophic mistakes and gross overexposure of workers.

This was indeed a new dimension in internal emitter research. No more waiting for a former dial painter to show symptoms or x-ray changes in bone or the slow realization that the uranium miners were developing lung cancer. This chapter takes up the major biomedical researches done on the fission products during World War II. The following chapter will review the second major new dimension, that posed by the production of plutonium and the transplutonic elements. Later, we will review the postwar work on fission products and actinide elements.

That the efforts were successful, and the knowledge sufficient for the times is seen in the fact that "... throughout the entire wartime period of activity of the Plutonium Project, there was not a single known episode of manifest radiation injury to the thousands of persons who worked on this program" (Hamilton 1949, p. 863).^(b)

II. The Fission Products

Before examining the biomedical work, we need a short summary to define the area of interest. Excellent reviews of the fission process are, of course, abundantly available. One of the earliest, and still an excellent one, is the summary of previously classified literature found in Glasstone's *Sourcebook on Atomic Energy* (1950). A more recent and very useful exposition can be found in the now classic text by Lapp and Andrews (1972).

The energy of the fission process is divided among kinetic energy of the fragments, prompt radiation, and fission-product activity. Lapp and Andrews (1972, p. 358) give 11% as the proportion of the total initial fission energy going

(a) True, the radioelements were isomers of stable elements already known, but the radioactivity component had the effect of making them "new substances."

(b) In view of the long latent period of chronic radiation effects, this statement must be viewed as implying short-term, relatively acute effects. Also, it would not include any criticality accidents where the problem is the prompt radiation released.

into fission product activity. For present purposes, we will consider only this and not the other 89% except in passing.

The fissile nucleus does not necessarily split symmetrically. At the relatively lower energies associated with thermal neutrons, asymmetric fission is more probable than symmetric. Only at exciting energies on the order of 400 MeV is symmetrical fission the most probable reaction. Furthermore, each individual fission is a unique event. The composition of fresh fission products is thus the result of a large number of probabilistic events. Nevertheless a fairly characteristic composition is seen: the now-classic bimodal curve of fission yield versus mass number. An example is seen in figure 6.1.

Note that the curve is for fission at thermal neutron energies and that it differs somewhat depending on whether the fissile material is ^{233}U , ^{235}U , or ^{239}Pu . Remember, too, that this picture applies only to fresh fission products. The decay of the short-lived components and the expression of the fission product chains soon change the composition.

FIGURE 6.1. The classic bimodal curve for fission-product yield from ^{233}U , ^{235}U , and ^{239}Pu . (Redrawn from Lapp and Andrews 1972, p. 359. Reprinted with permission of Prentice-Hall, Inc., Englewood Cliffs, New Jersey, copyright 1972.)

As Glasstone eloquently pointed out, the mixed fission products soon after formation are mixtures of great complexity. Much research was necessary to devise methods for identification and isolation of individual products and chains. Fortunately for the biomedical scientist, some simplifications could be applied. First, the radiation dose from fresh fission products decreases as a power function of time, as might be expected from a mixture decaying exponentially with a wide variety of decay constants. The exponent varies with the starting material and energy of the exciting neutrons. The classic rule espoused by Way and Wigner (1948) is an exponent of -1.2 after the initial, very short-lived nuclides have decayed out.^(a)

Second, since a large number of the products have short half-lives and/or decay by chains, it is possible to identify a few nuclides of predominant importance to living organisms.

Third, the radiations are predominantly beta and gamma. Thus, to some extent the experience with x rays and radium gammas could be utilized for the gamma components. Entirely new research and theory were needed for the beta-particle effects. These had been studied with cyclotron-produced elements. Parker (1943) prepared an early informative summary.

The challenge to biomedical research on the fission products was to identify those elements of significant fission yield, of sufficient half-life to be significant yet not so long as to deliver only a minuscule dose over times of interest to worker protection, and then zero in on characterization of their metabolic behavior and their acute and long-term effects. Obviously, such a simplification was essential. It was successful as we shall see. There was also need to characterize the biomedical problems of mixed fission products. This was emphasized in research on the characterization of the quality and quantities of radiation emitted under different conditions of production, storage, and eventual handling of fission products as nuclear waste.

III. Tracer Studies at Berkeley

A. The Modus Operandi

The cyclotron at Berkeley that produced many of the radioisotopes discussed in chapter 5 was a 37-in. machine housed in an old wooden building called "The Radiation Laboratory" (a far cry from the radiation laboratory of later years). Near the end of the decade of the 1930s, the University of California at Berkeley acquired two buildings that have played host to much important biomedical research. The first was the Donner Laboratory. The second was the Crocker Laboratory, sponsored by a San Francisco banker whose family fortunes had come from the gold rush and the Southern Pacific railroad. The latter was opened in 1939, and almost immediately a 60-in. cyclotron was installed in it. Combined with the older 37-in. machine, which remained in the Radiation Laboratory, this machine enabled much progress toward providing fission products for biomedical research in the early years of World War II, even before the nuclear fission reaction had been proven feasible.

Hence, as war work began to look inevitable, the Berkeley laboratories were not only fully prepared, they were already under way to a degree. The Donner

(a) The more complete formulation is $\frac{dE}{dt} = (3.9t^{-1.2} + 11.7t^{-1.4}) \times 10^{-6} \text{ MeV sec}^{-1}$ (Lapp and Andrews, 1972, p. 366).

Laboratory was partly diverted from things biomedical and became headquarters for Ernest Lawrence's wartime team, a host of visitors, and the Calutron Project administration. A young physician, Joseph G. Hamilton, whom we met in chapter 5, and who had plans for a major effort with ^{32}P for the treatment of leukemia, was chosen to direct the Crocker Laboratory. Interestingly enough he even had ideas for possible therapy of bone tumors with a new radioisotope of strontium which was found to localize in bone (Pecher 1941; Pecher and Pecher 1941).

A systematic study of the metabolism of the fission products of uranium was begun on October 15, 1942. Note that this preceded by about two months the success of the chain-reacting "pile" in Chicago. The fission products were derived from the bombardment of uranium targets by deuterons in the 60-in. cyclotron, not from nuclear reactions in a pile (reactor). They continued to be so produced throughout the work, long after pile-produced fission products could be made available. The reasons for this were largely technical. The problems of preparing carrier-free isotopes from the cyclotron targets had been or were being worked out satisfactorily. It was a long time before comparable separations could be made from the complex mess of reactor fission products. Also, the radiation levels from the products of the cyclotron were much easier to cope with than reactor fission products. Thus, it seemed better to proceed as rapidly as possible with a well-established technique.

But the quantities of fission products produced in the cyclotron were quite limited. Thus, all of the Berkeley experiments were strictly at the tracer level. No studies of effects could be done there. These were performed in other parts of the Plutonium Project.

Hamilton was joined in the endeavor by several whose names will not be forgotten. One was Kenneth Scott, a recent graduate student who had already been involved with possible therapeutic uses of isotopes. Others included Harold Copp, Dorothy Axelrod, Josephine Crowley, Henry Lanz, Lester Van Middlesworth, and, as a technical assistant, Patricia Wallace (now Patricia Durbin), who provides invaluable continuity to the entire effort. (More in chapter 8.) Advice was made available by senior scientists such as I. L. Chaikoff and D. M. Greenberg and, of course, it all grew under the watchful eyes of Robert Stone and Ernest Lawrence. Early in the project, Hamilton persuaded two soil scientists from the Agriculture School who were not involved in war work to join him as chemists. These were Roy Overstreet and Louis Jacobson, who did the majority of the radiochemical preparations of the carrier-free fission products from the irradiated targets.^(a,b)

- (a) While the personnel involved in the Berkeley work are identified in the monthly and other progress reports, as well as in the later publications, referenced in the bibliography to this chapter, much personal and anecdotal information was obtained from Dr. Patricia Durbin who began work at the Crocker Laboratory as a "Diener" in July 1946 and who has been there ever since. I am greatly indebted to her for a personal interview in October 1979 and for a transcript of a paper she gave at a history session of the combined Health Physics and Radiation Research Society meetings in San Francisco in July 1974. The latter was not published, but the organizer and chairman of the program, Dr. Ronald Kathren, provided me with a transcript of the tape.
- (b) While all of the war enterprises were strictly group efforts, each had its key personnel. A fascinating review of the chemistry group at the Metallurgical Laboratory has been provided by Seaborg (1977-1980). We cannot provide the same detail, but Appendix B attempts to provide a much-compressed "Who's Who."

Reports of the California work began to appear almost immediately in the classified monthly reports of the Plutonium Project. A few selected ones are given in the reference section under Metallurgical Laboratory (1942; 1943a,b,c; 1945a,b; also Hamilton 1943b, 1944).^(a)

By 1945, summary-type reports began to appear (e.g., Hamilton 1945). Others were prepared for what was known as the Project Handbook.^(b) Many were included in the National Nuclear Energy Series (NNEs) volumes, including some that were never published. (See "NNEs Hiatus," Appendix C, where the paper titles are listed and the abstracts given.)

A very complete summary document was prepared by the California groups before declassification permitted open literature publication. It was later available as a Manhattan District Declassified (MDDC) report (Scott et al. 1947). With 209 pages, this report gives more detail on the preparation of the materials than any of the published works. It has separate chapters for strontium, barium, yttrium, cerium, praseodymium, zirconium, ruthenium, tellurium, iodine, xenon, cesium, and "Fission Product Mixture." Fortunately, except for the important information on techniques and that on the fission product mixture, all of the information also reached the open literature (Hamilton 1947, 1948).

B. The Results

A fairly standard format was used: three rats per group and usually four elapsed time periods per isotope and per dose. Thus, twelve rats were involved for each progression, three for each point. This has been viewed as marginally small by many subsequent investigators. Yet, the information gained in these almost pilot-type experiments has stood up exceedingly well. And it should be remembered that amounts of the isotopes were quite limited. Indeed, there was not enough for three rats per point in some instances.

In addition to the two published reviews by Hamilton already cited, a rather similar one was published in the *New England Journal of Medicine* (1949), and declassified papers on specific elements were scattered through both the Atomic Energy Commission (AEC) and the regular published literature. A most useful compendium on strontium and calcium is the one by Wasserman and Comar (1961), which gives an insight into both the Project literature and subsequent published papers.

Tracer studies involved parenteral injection, oral ingestion, and intratracheal instillation. Since the results of the latter work were only qualitative, it will not be discussed here. In addition to radiochemical measurements, there was an extensive program of autoradiography, which was employed to characterize distributions within tissue. The quantities administered were usually in the range of 0.58 to 5.0 μCi , thus assuring no modification of transfer kinetics and localization by radiation damage. Feces and urine were separated in special metabolism cages developed in the Department of Physiology.

(a) Few complete sets of these monthly reports now exist. The most useful set is in the hands of Dr. Hymer Friedell, professor of radiology emeritus at Case-Western Reserve Medical Center. I am much indebted to Dr. Friedell for the opportunity to go through his files and make copies of the most pertinent documents.

(b) This became the basis in part of the postwar monographs prepared in each laboratory and known as the National Nuclear Energy Series. We will cite many of these as we progress.

Sometime in 1943, a summary table (table 6.1) was prepared (Durbin 1976). Information on fourteen fission products could be given, including parameters such as oral absorption, accumulation in principal organs of retention, and rate of elimination therefrom. Consider that this was from a project begun in mid-October 1942! Under today's conditions, the paperwork for the supporting funds would have barely been completed in that period of time.

TABLE 6.1. Summary of Early Fission Product Studies

Radio-element	Half-life	Fission Yield (%)	% Oral Absorption	% Accumulation in Principal Organ of Retention	Rate of Elimination from Principal Organs of Retention	
Sr ⁸⁹	53 d	4.6	5-60	70% bone	bone	>200 d
Sr ⁹⁰	25 yr					
Ba ¹⁴⁰	12.8 d	6.1	5-60	60% bone	bone	>50 d
I ¹³¹	8.0 d	2.8	100	20% thyroid	thyroid	>30 d
Cs ¹³⁵	33 yr		100	45% muscle	muscle	15 d
Y ⁹¹	57 d	5.9	<0.05	65% bone	bone	>500 d
La ¹⁴⁰	40 hr	6.1	<0.05	70% liver	liver	10 d
				30% bone	bone	>25 d
Ce ¹⁴¹	28 d	5.7	<0.05	50% liver	liver	10 d
Ce ¹⁴⁴	275 d	5.3	<0.05	25% bone	bone	>100 d
Pr ¹⁴³	13.8 d	5.4	<0.5	35% liver	liver	10 d
				50% bone	bone	>100 d
61 ¹⁴⁷	3.7 yr	2.6	<0.05	55% liver	liver	10 d
				35% bone	bone	>100 d
Zr ⁹⁶	65 d	6.4	<0.05	35% bone	bone	>100 d
Nb ⁹⁵	35.15 d	6.4	<0.5	30% bone	bone	30 d
				25% blood	blood	1 d

Ru ¹⁰³	42 d	3.7				
Ru ¹⁰⁶	1 yr	0.5	<0.05			
Te ¹²⁷	90 d	0.033	25	15% blood	blood	15 d
Te ¹²⁹	32 d	0.19	25	6% kidney	kidney	15 d
Xe ¹³³	5.3 d	4.5				

Source: Modified and reset from Durbin 1976.

By February of 1944, the first phase of the fission product work was completed, and the first samples of plutonium arrived for metabolic study. This captured the lion's share of interest at Berkeley from then on. A table similar to table 6.1, but listing also the properties of plutonium and related elements, is given in the Berkeley group's first major open literature publication (Hamilton 1947), from which the following salient points concerning fission products can be summarized:

1. Localization in bone is quite common after parenteral administration.
2. Only five of the studied fission products are absorbed significantly from the digestive tract. These are strontium, barium, tellurium, cesium, and iodine.
3. The pattern of distribution following oral absorption is indistinguishable from that after parenteral administration.
4. As was already known, iodine deposits selectively in and is retained fairly avidly by the thyroid tissue.

5. Some of the nuclides deposit initially to a considerable degree in liver but leave this organ quite rapidly while being retained by bone. These are lanthanum, praseodymium, cerium, and what was then known as element 61 (now promethium). This deposition did not appear to be in reticuloendothelial system (RES) elements since spleen and bone marrow did not show similar accumulations.
6. Other soft tissues retained relatively small amounts, although spleen and kidney might reach from 0.1 to 0.25 of the bone content after two months or more.
7. Xenon acts entirely independently as would be expected from a relatively unreactive gas. It is quickly absorbed through the lungs and quickly eliminated.
8. Loss from bone is usually quite slow, as illustrated in figure 6.2, taken from Hamilton (1947). (Contrast the picture shown in figure 6.2 with that seen for the deposition and elimination from liver as shown in figure 6.3, also taken from Hamilton 1947.)

FIGURE 6.2. Early depiction of bone uptake and retention of several fission products as indicated. (Redrawn from Hamilton 1947, p. 329. Reprinted with permission of Radiological Society of North America, Oak Brook, Illinois, copyright 1947.)

These results did much to simplify the problems of understanding these new radionuclides; particularly in the context of worker protection. The alkaline earths and rare earths deposited in bone, with or without temporary residence in other tissues like liver. The experience with radium could be applied to these, *pro tem* at least, with appropriate corrections for the different metabolisms.

FIGURE 6.3. Illustration of the relatively rapid elimination of several fission products from liver. (Redrawn from Hamilton 1947, p. 331. Reprinted with permission of Radiological Society of North America, Oak Brook, Illinois, copyright 1947.)

The remaining five fission products from the list of biomedically important ones, ruthenium, tellurium, cesium, xenon, and iodine did not localize to any degree in skeleton. But, except for the special case of iodine, they showed no marked concentration in any other tissue, and they were excreted much more

rapidly than the bone seekers. On this basis, it could be concluded that these elements did not pose as great a hazard as the alkaline and rare earths.^(a)

The work with purified, uranium-free but unseparated fission products appeared largely in Project reports, e.g., Scott et al. (1947). The mixture used was "cooled" eighty-seven days before injection. While there were some puzzling inconsistencies, on the whole, the mixture behaved like a summation of its components, largely strontium and barium.

The autoradiographic work, seen to largely it seems by Dorothy Axelrod, brought some surprises. These are pertinent to the current chapter and even more pertinent to our consideration of the actinides and transuranic elements. Figure 6.4 is a now classic picture showing a photomicrograph (upper) and an autoradiograph (lower) of the femur of a rat one week after receiving 5 μ Ci of radioactive strontium (presumably ^{89}Sr). The autoradiograph shows the strontium deposited relatively evenly through the mineral structure. This was much like radium and calcium, and no surprise. But practically none of the other bone-seeking fission products showed such a distribution. Instead, they, like plutonium (see chapter 7), were deposited on endosteum, periosteum, and in the region of trabecular bone. Yttrium, zirconium, and cerium behaved in this manner. An illustration taken from Hamilton's review (1947) is seen in figure 6.5. The adult rat received 10 μ Ci of zirconium and was sacrificed twenty-one days later.

Clearly, the microdistribution of the radiation dose from such a deposition would be quite different from that characteristic of strontium and radium. It was now clear that there were at least two kinds of bone-seeking elements. The ramifications of these findings, seen first in the Berkeley work, have occupied the attention of those interested in bone-seeking elements and the physiology and biochemistry of bone ever since.

This summarizes the major findings from the broad exploratory work at Berkeley. With a group so large and diversified, obviously there was some

(a) An indication of the general tendency to use the results for gauging of hazard can be found in the following excerpt from a letter to C. M. Cooper from J. G. Hamilton, dated July 27, 1943, on Metallurgical Laboratory stationery:

I should like to point out in the first place that under these circumstances radio-ruthenium, on the basis of its abundance, is far more of a potential hazard than either the 8 day Iodine or the 5 day Xenon, since these two radioelements have relatively short half-lives and their abundance at the time of chemical extraction would be many times less than that of the ruthenium. In addition, the beta-rays from the 30 second rhodium daughter of the 200 day radio-ruthenium are extremely energetic. It was my understanding that present plans at W contemplate the use of either tetra-valent cerium or bismuthate as the oxidizing agent for the product. As you recall under these conditions ruthenium is converted to the volatile tetroxide, Dr. Coryell told me today that they found under small scale test conditions as much as 15% of the ruthenium present in the solution was volatilized during the oxidation. You may recall from the discussion at the Laboratory Council Meeting of July 12th that it was stated that ruthenium when introduced into the lungs was retained to a high degree for periods of time ranging up to 16 days. In this particular instance the ruthenium was introduced in the tetra-valent state. However, it is probable that any ruthenium tetroxide which might be inhaled would be very promptly reduced by the tissue fluids within the lungs. The experimental work in Berkeley indicates that some of the fixed ruthenium in the lungs will be slowly released and eliminated. . . .

FIGURE 6.4. Early photomicrograph (top) and autoradiograph (bottom) showing distribution of radioactive strontium in rat femur one week after intraperitoneal injection. Note the distribution to the sites of bone mineral and deposition in calcifying trabeculae beneath the epiphyseal plate. The similarity to calcium is notable. (From Hamilton 1947, p. 333. Reprinted with permission of Radiological Society of North America, Oak Brook, Illinois, copyright 1947.)

FIGURE 6.5. Early photomicrograph (top) and autoradiograph (bottom) of rat femur 21 days after injection of radiozirconium. Note the lack of deposition in mineral matrix. Zirconium is just one of several fission products that appear to be “surface” rather than “volume” seekers (see text). (From Hamilton 1947, p. 337, utilizing in part data from unpublished wartime studies. Reprinted with permission of Radiological Society of North America, Oak Brook, Illinois, copyright 1947.)

opportunity for peripheral investigations. When it was clear that the elements of most concern among the fission products were bone seekers, Harold Copp and his group investigated possible therapeutic removal. This was much like the work described for radium in chapter 1, and was about equally unsuccessful. Age was studied as a variable, and the expected greater uptake by the young was shown. Mechanisms were mused about even though time did not allow much active research to check out ideas. The facts of bone remodeling began to emerge (Jones and Copp 1948). Effects of diet and disorders such as rickets were looked at (Jones and Copp 1951).

A comparison of radiostrontium uptake by adult, young, and young rachitic rats taken from the work of Copp and colleagues and presented by Durbin (1976) is shown in figure 6.6.

FIGURE 6.6. Comparison of strontium uptake by young normal, young rachitic, and adult rat skeleton. (Redrawn from Durbin 1976.)

Toward the end of the period, the Berkeley group added some bona fide inhalation experiments with characterized aerosols of fission products. These substituted for the earlier unsatisfactory intratracheal instillation work. Discussion will be reserved for the chapter on inhalation toxicology (chapter 9).

Finally, it is pleasing to see that Jacobson and Overstreet, who had been recruited into being the radiochemists, got a chance to use some of the radio-nuclides at hand in experiments related to agriculture—their home base. They published a study of the mechanism of ion absorption by plant roots using isotopes of rubidium, strontium, and iodine (Jacobson and Overstreet 1947) and an in-house report on uptake of yttrium, cerium, strontium, tellurium, zirconium + columbium, as well as plutonium by barley and dwarf pea plants (Jacobson and Overstreet 1945).

There were many others, but these should give the flavor of the “side-show” researches accompanying the main study, along with the fact that the main study turned to the inhalation route, the most likely mode of worker exposure, when adequate quantities of material and techniques were available.

C. Postlude at Berkeley

The end of World War II did not end fission product research at Berkeley or anywhere else. Indeed, after a short interlude, work was resumed with new vigor and in new dimension as we shall see in chapter 8 and others. Yet, an era ended for the Crocker Laboratory during the immediate postwar years.

First, there were personnel changes. Ken Scott went across the Bay to the medical campus in San Francisco to run its radioisotope laboratory. Jacobson and Overstreet went back to the School of Agriculture. Harold Copp went to British Columbia. The Donner Laboratory became again a medical research institution, and John Lawrence returned to his brother's side and managed space and finances for training, both formal and apprentice-type, of scores of "students," many of them quite senior coming to learn about the new field of atomic energy and radioisotopes.^(a) Formal courses were started, including one by Joe Hamilton. Pat Durbin obtained a Ph.D. in chemistry and became much more than the diener and animal tender she says she was during the war (Durbin 1976, 1979).

Nevertheless, and despite these other activities, Hamilton and his staff continued tracer studies with fission products going on to the less abundantly produced elements. Durbin relates that this process was known affectionately among the staff as "chewing our way through the periodic table" (Durbin 1976), remarking that next to the 60-in. cyclotron the periodic table held the greatest fascination for Joe Hamilton. By 1959 to 1960, most of the elements from fission and many others of interest had been studied. Attention turned to problems that there had not been time to attack during the war years. This resulted in (1) a University of California Radiation Laboratory report on the localization of ^{144}Ce in fetal rats, (2) a study on the distribution in the rat of radioisotopes of some heavy metals, and (3) a study of the lanthanides. These are detailed in chapter 8.

Joe Hamilton died of leukemia in 1957. In 1960, the 60-in. cyclotron was dismantled, and later the laboratory became a parking lot. The cyclotron magnet is at work in a reincarnation of the Crocker Laboratory built on the campus of the University of California at Davis (Durbin 1976; Seaborg 1980). The 37-in. cyclotron from the old "Radiation Laboratory" now resides in the Lawrence Hall of Science on the Berkeley campus. Its large magnet was used during the war years in the Calutron project.

A photograph of the Crocker Laboratory at Berkeley is shown in figure 6.7.

IV. Fission Product Research at Chicago

A. The Modus Operandi

Work on the fission products in the Chicago section of the Metallurgical Laboratory seems not to have begun so early nor to have been so neatly packaged as the work at Berkeley. The early monthly reports speak first to setting up apparatus for study of radioactive xenon (Metallurgical Laboratory Monthly Reports, September 1942, February 1943, et seq.), also for xenon and argon together. Very soon, they address subjects such as "Hazard from Inhaled ^{131}I "

(a) Even during the war nearly everyone had at least a few months at Berkeley; but then it was all classified and in very specific one-to-one relationships, which waxed and waned as quietly as possible.

FIGURE 6.7. Photograph of the Crocker Laboratory on the University of California Berkeley campus, home of the 60-in. cyclotron and much of the early work on fission products and actinides. Building has been demolished since this photograph was taken. (Courtesy of Dr. P. W. Durbin.)

and "Hazards from Fission Products." Results are only sketchily given in the monthly reports. In the early months, more attention was paid to other plans for the Chicago project.^(a) But by April 1944, a substantial section was devoted to "radioactive materials, mammals." This section includes xenon, ruthenium, iodine, ^{89}Sr , ^{140}Ba - ^{140}La , ^{32}P , and fission product mixture in small rodents, along with descriptions of the distribution and effects of fission mixture in goldfish. But biological results do not begin to appear in earnest until the monthly reports of early 1945. From then on, there was a mounting crescendo of inhalation, ingestion, and comparative toxicity experiments from the Chicago group.

The reasons for this different tempo and approach at Chicago compared to Berkeley appear to be at least twofold. First, the orientation was more toward effects, i.e., toxicology, in addition to the metabolic behavior of the elements. Second, the much larger quantities of material thus needed required waiting for a supply of fission products from the reactor at the Clinton Laboratories in Oak Ridge, which started operation in the latter part of 1944.

We have already addressed the early problems of establishing techniques for fission product separation and purification, but they need some elaboration. A typical example of what had to be gone through initially to get fission products,

(a) The general problems of uranium toxicity, personnel protection, neutrons, and external radiation filled these early reports along with projections for the Berkeley work.

in this case radiobarium and radiostrontium, ready for biological use is seen in the following letter, reproduced in part, from Waldo Cohn to R. D. Finkle dated December 1943 (Cohn 1943). Dr. Finkle was preparing to manage a block of the fission product work at Chicago, and Dr. Cohn was at the "pile" at the Clinton Laboratories.

Dear Ray:

... At this time we had all the Ba and Sr of the PbSO_4 precipitates, (except the 95 mC) in two small tubes, one being the BaCl_2 precipitate, the other the supernatant which should contain the Sr. The lead had gone over to the Sr in the course of HCl-ether washings of the Ba precipitate, we reasoned (and no PbS came down on testing with H_2S).

The Sr fraction was cleared of Ba by adding another 0.5 mg Ba, evaporating, dissolving in 0.5 cc and adding 5.5 cc of HCl-ether mixture (4-1/2:1). The precipitate turned out to have 6-1/2 times the activity of the first Ba precipitate. Since the chemical Ba was the same we decided to combine both Ba precipitates. We now had an Sr solution free of active Ba, containing Pb, and two 0.5 mg Ba precipitates. Okay so far?

At this point I had better warn you that our assays with survey meter of Hume's counter have been found to be in error due to at least two factors: one, contamination of glassware due to absorption—hot, strong acid seems to be the only way to get all adsorbed activity out; two, contamination of glassware due to the deposition by recoil in the structure of the glass itself of daughter La from Ba decomposition. This can't be removed. Hence some of our tubes and flasks had high counts to start with (unbeknownst to us) and we had no guarantee that all the activity in a container would come out easily or dissolve for reprecipitation, etc. Also, we were depending on γ activity for such scouting. Lastly, every container or pipette used adsorbed some of the activity. This we are recovering along with the losses to be mentioned in a moment.

... I can't impress on you too strongly the need for devising ways and means to get around adsorption and contamination. We are designing leucite containers and syringes for shipping and injecting; we will try to get such built quickly. We may have to use 1 or 1/2 mg of carrier, since the slugs are too pure, until we can lick the adsorption problem here.

Hand and apparatus contamination have plagued us throughout. The whole lab must be thoroughly cleaned up to be safe. Nor would a "hot lab" have helped us to do anything on prevention of hand and body overexposure. Two things will: more manpower per operation, and a great deal of care and forethought in devising and planning experiments and equipment to do the job safely. We have been the first to do such work on the Curie-level, and we have learned a lot about how not to do it. We think we know now how to proceed, but we must build the equipment and work more slowly at first. So don't rush us; we are piloting a rather dangerous and tricky business. If you can spare manpower, for a week or ten days, we can move faster. There are only three of us to do the job, and this is the place to do it.

If Ed gets over 5 mC Ru we will send it up with the Sr and Ba now going through. Then, after scrubbing the lab, we will try for 200 mC of mixed F.P.s. And it is no hand job—not with what we know now.

(Cohn 1943, pp. 1, 3)

B. Results

Full-length papers from the Chicago work were issued first as classified in-house reports. Many of these were later prepared for the three volumes of the NNEs that did not get published (Appendix C). Others were issued only as declassified in-house documents and were not slated for publication. Many reached the

published literature in the immediate postwar period or were presented in part in various summaries and symposia.

1. Earlier Work

A general review of this earlier work gleaned primarily from in-house reports is given below:

a. A report by Tompkins, Broido, and Teresi (1946) gives a further insight into the development of radiochemical procedures used in much of the Chicago work on fission products. A quotation from the first page follows:

... This program involves the study of the biological effects of radioactive isotopes, including the products of uranium fission, which must be prepared in a radioactively pure form without added carrier and with very little extraneous solids.

At the time the laboratory was established, none of the fission products was available in pure form, so the emphasis was principally on the separation and purification products without added carrier. As this work was taken over by the Clinton Laboratories and stock solutions of purified radioactive isotopes became available, the operations in the laboratory were reduced to the withdrawal of aliquots of these stock solutions and the preparation of these aliquots for use in the Section. Since preparations were diversified, it was not feasible to develop a special apparatus for each preparation. The techniques and equipment have, therefore, been developed to approximate standard laboratory practice as closely as possible. The principal requirement has been for the handling of pure beta emitters at levels under 100 mc since most of the experimental work has been concentrated on the use of this type of material.

The paper describes the many special tools they devised for handling the beta and beta-gamma emitters, with special emphasis on avoiding what they considered the worst hazard, reaching over a shield and working from above the "hot" sources.^(a)

b. The barium-lanthanum couplet was investigated quite early. A brief description of the methods employed is given in a report by R. D. Finkle, Snyder, and Tompkins (1946), and the metabolism and acute radiotoxicity by Snyder et al. (1946). An important objective of the experiment was to compare the metabolism of toxic levels with the tracer levels used in the work at Berkeley. They were strictly comparable in general except that large (i.e., lethal) doses were retained more completely in the skeleton of the rat than lower doses. Effects of the barium-lanthanum couplet on weight and food intake (Snyder, Sacher, and Teresi 1946) showed definite growth retardation at about half the midlethal dose for each species. The midlethal dose in one month was about 3 to 5 $\mu\text{Ci/g}$ (R. D. Finkle, Snyder, and Kisieleski 1947). Finally, Jacobson (1946) reported that the hematological effects were of the threshold type and indicated damage to

(a) Radiochemical purity of these sources has not been fully established. In the atmosphere of urgency, the Chicago investigators had to be satisfied with what they got, although checks were made that would have detected any gross errors or mislabeling. The purity improved rapidly with time as techniques were perfected. But we must assume that some of the earlier preparations had up to 10% contamination, perhaps more, especially with closely related isotopes such as ^{90}Sr in ^{89}Sr , ^{239}Pu in ^{238}Pu , ^{241}Am in ^{239}Pu , etc. (Kisieleski 1980; Norris 1978). The investigators closest to the work did not view the problem as serious, and it was relatively transient. But it does appear that the composition of injection solutions was largely taken on faith from the label and shipping information. Even at the time, tracing to specific batches at Oak Ridge was difficult, and it is, of course, impossible now (Kisieleski 1980).

bone and marrow because of deposition of the barium in bone and damage to spleen, lymphatic, and epithelial tissues primarily from the lanthanum deposited in soft tissues.

c. Among the early reports concerning metabolism and acute effects of strontium is a series by David Anthony and colleagues (Anthony, Lathrop, and R. D. Finkle CH-3844, MDDC-1540, no date; Anthony, Lathrop, and R. D. Finkle CH-3846, MDDC-1363, 1947; Anthony, Lathrop, and Snyder CH-3845, MDDC-1364, 1946; Simmons and Jacobson, CH-3797, MDDC-1387, 1946). The rapid loss from the body in the first three days noted in the Berkeley work was reiterated and expanded to include mouse and rabbit. After ten to fifteen days, virtually no more strontium was excreted. There were species differences in total excretion, however, with the most occurring in the rabbit and the least in the rat. The acute lethal dose in thirty days (LD_{50}) was between 7 and 8 $\mu\text{Ci/g}$ of ^{89}Sr - ^{90}Sr when received by the intraperitoneal route in mice, somewhat less, about 5 $\mu\text{Ci/g}$, in rats and rabbits. Concentration in bone after the first three days was more than one hundred times that in soft tissue. Blood changes were of the threshold type, with heterophils being the first to show changes.

d. An interesting correlative experiment was done with ^{32}P . This is, of course, not a fission product and was available before the war in sufficient quantity to support metabolism studies in humans and a beginning of therapeutic use. On premises akin to those for the use of radium as a bench mark, Anthony and Snyder (1947) embarked on a toxicologic study of ^{32}P for correlation with and as something of a base line for the fission product studies. A rather extensive program was planned, but only the so-called pilot studies could be completed because of the exigencies of other war work.

Nevertheless, the results were considered important for the possible extrapolation to man of work with the less-known newer elements, and they facilitated planning of later work.

To quote from the abstract of MDDC-881 (Anthony and Snyder 1947):

1. Data were obtained on the toxicity of a well-known radioactive element in the same strains of animals and under the same experimental conditions as data obtained with less familiar radioactive elements. Determinations of the relative radiotoxicity of different isotopes could therefore be made without reference to work done under different conditions.
2. Since the effects of radioactive phosphorus on man had been studied, comparison of the effects with those on laboratory animals provided a basis for extrapolation with other radioactive elements.
3. The experiments with radioactive phosphorus greatly facilitated planning and interpretation of later experiments on the toxicity of other heretofore rare radioactive elements.

The animals (ABC mice) received doses from 8.4 to 0.55 $\mu\text{Ci/g}$ by intraperitoneal injection. There were two series, one for metabolism and toxicity and one for serial sacrifice and study of pathology.

Retention in tissues is shown in figure 6.8, reproduced from figure 3 of the subject document.

Loss is quite rapid except from femur and brain and seems to be consistent with a power function of time, which appears with impressive regularity in most of the Chicago metabolism work on bone-seeking elements. There was no significant effect of dose on the pharmacokinetics. The LD_{50} is in the vicinity of

FIGURE 6.8. Concentration of ^{32}P in femur, liver, muscles, gastrointestinal tract, and brain. (Redrawn from Anthony and Snyder 1947.)

4 $\mu\text{Ci/g}$ body weight, but the experiment was too small to attach great significance to the figure. For what it is worth, it appears similar to that of the fission products.

There were no grossly visible lesions in the mice that died acutely. Some survivors developed tumors, but these are not discussed.

e. Cerium was in some respects a more complex problem than strontium. A considerable portion of an initial dose of cerium deposits in liver, while the rest goes to bone. Its distribution represents the rare-earth and rare-earth-like group of radioelements, which includes yttrium. Cerium-144 has a fairly long half-life (275 to 300 days) with a shorter-lived (17 to 18 min) daughter, ^{144}Pr , which is highly energetic (~ 3 MeV). The initial deposition in liver gradually leaves and goes to bone or is excreted. Unlike strontium, excretion of these is relatively slow.

The early changes involved liver more than bone with sometimes very few of the common lesions noted in radiation toxicology. The LD_{50} for 30 days in the rat was about 3 $\mu\text{Ci/g}$ and for 120 days somewhat lower.

2. Fission Products as Carcinogenic Agents

As soon as the work on acute toxicity was well established, the Chicago workers began to think about potential carcinogenicity of the new elements produced in fission. Because of the experience with radium, attention focused on the bone seekers. "The Manhattan District was determined not to encounter a delayed surprise such as that which greeted the radium painting industry. . . ." (MDDC-145, p. 1). But the interest extended as well to soft-tissue cancers.

A rather considerable effort was mounted quite early in the Met Lab's work. A major portion of the experiments concerned ^{89}Sr and plutonium, but there

were pilot experiments with radium, cerium-praseodymium, ^{91}Y , and the effect of age on bone tumor development.

The first moderately complete report of this large experiment (MDDC-145) was written probably in 1945 (no date is attached to the manuscript) and declassified in July 1946 (Brues, Lisco, and M. Finkel 1946).^(a) Some of the results were included in summary form in the special issue of *Radiology* published in 1947 (Lisco, Finkel, and Brues 1947).

There were 3,090 mice in an experiment with ^{90}Sr . Half received single doses ranging from 0.05 to 5 $\mu\text{Ci/g}$, while half received monthly injections ranging from 0.01 to 1 $\mu\text{Ci/g}$ each month. (About 80% of the injected strontium is lost between injections.) The route of injection is not specified. It was probably intramuscular. The mice were about equally divided between Carworth CF1 strain and ABC hybrid mice. In addition, Sprague-Dawley rats and a few rabbits and dogs were introduced for species comparison.

The first finding was that radiostrontium can be a very potent carcinogen to bone in sufficient concentration. This was noted in mice injected by C. L. Prosser in an initial group of animals done 850 days before the preparation of the first report. Lymphoma incidence was not demonstrably increased, although some of the animals showed a blood picture suggestive of leukemia. Mammary tumors were in low incidence in the animals receiving strontium. Metastases of the bone tumors were numerous, especially in the rats.

Noncancerous changes seen after ^{90}Sr were greying of the hair in pigmented mice receiving over 1 $\mu\text{Ci/g}$ and the usual leukopenia, lymphopenia, and hypochromic anemia.

Cerium-praseodymium deposits to a considerable extent in liver, as described earlier. These animals showed both bone tumors and marked changes in liver, e.g., complete atrophy (except along the lower margin), ascites, and jaundice.

Finally, rats were fed ^{91}Y by stomach tube to determine effects of a largely unabsorbed element in the fission product group. Report MDDC-145 states that the LD_{50} for a single feeding in the rat is 20 mCi/kilo (i.e., 20 $\mu\text{Ci/g}$), a factor of five to ten above the corresponding parenteral doses of fission products. In a somewhat more detailed report, Lisco et al. (1947) reported carcinoma of the colon in rats receiving the large single feeding. A second group given seventy-eight feedings of 0.06, 0.20, or 0.46 mC of ^{91}Y over a three-month period did reasonably well, except for superficial ulcerative lesions of the colon, which were eventually serious enough to cause death.

It seems very likely that these reports are among the very earliest ones to prove the carcinogenic potency of the fission products. They were the first wave of a long series of large experiments at Argonne with small rodents, using a variety of beta- and beta-gamma-, as well as alpha-emitting radionuclides. (See subsequent sections and chapters.) They proved that the beta particle was not qualitatively different from alpha particles or gamma rays in inducing cancer in animals.^(b)

The extension of the work at Chicago under the aegis of the Argonne National Laboratory (ANL) will be considered separately from the work sponsored by the Manhattan Engineer District (MED) work concentrated upon in

(a) There were three individuals in the Chicago work with very similar names: R. D. Finkle, Miriam P. Finkel, and, as we saw in the chapter on radium, Asher J. Finkel. Where there is a chance of confusion, we will try to attach the appropriate initials.

(b) The probable mechanisms of the biological action of beta particles were discussed by Parker (1943).

this chapter. But it should be remembered that the groundwork was laid, the personnel and techniques already assembled, indeed some of the long-term experiments started by the middle and late-middle 1940s.

3. Transmission from Mother to Offspring

There was naturally a strong desire to know whether or not these new radioelements would produce greater or qualitatively different effects on the growing fetus as was fast becoming apparent in the work using external radiation sources. Also, it was important to know the extent to which they might pass the placenta or be secreted in the milk of lactating mothers. Miriam Finkel undertook such studies in the Met Lab Biology Division at Chicago. They were reported in the AEC literature and published relatively early (Finkel 1947).

Radiostrontium (^{89}Sr) was given intraperitoneally to prospective rat and mouse mothers and supplementary information obtained from one pregnant dog, which received ^{89}Sr intramuscularly.

The results were quite complex, partly because the interval between receipt of the dose and delivery seemed to make more difference than many other factors. But some generalizations can be made:

1. Strontium-89 passes readily from parent to offspring.
2. Doses of 2.5 or 5.0 $\mu\text{Ci/g}$ before conception reduced the number of litters.
3. Treatment during pregnancy using 5 or 10 $\mu\text{Ci/g}$ increased both the fraction of totally stillborn litters and the number of stillborn young in viable litters.
4. Uptake of ^{89}Sr by the fetus varies considerably during gestation. It is almost negligible up to the third quarter and is greatest during the last days of gestation.
5. Pregnant mothers receiving radiostrontium lived longer than nonpregnant animals. It is thought this reflects the fairly large portion of the dose that goes to the fetus rather than irradiating tissues of the mother. This would, of course, reduce the dose to the mother.
6. There is a higher specific activity in the newborn mouse than in the mother at the time of delivery.
7. Initial excretion of ^{89}Sr is much lower in very young mice than in adults.
8. Animals receiving doses in utero show retardation of growth, anemia, bone malformations, and, in a few instances, osteogenic sarcoma.

Although the results are all given in terms of activity units injected rather than radiation dose (as is true of all of Dr. Finkel's work), and thus comparison with external radiation sensitivity is not easy, the author makes the statement that "there is no indication that fetal and very young tissues are either more or less sensitive to Sr^{89} than are adult tissues" (M. P. Finkel 1947, p. 420).

4. Fission Products and Goldfish

Even before the interest in fisheries at the Hanford Site was generally known (see chapter 11), the Chicago group studied the accumulation and distribution of radiostrontium, barium-lanthanum, fission mixture, and sodium in goldfish. It is hard to believe that the motivation for this work represents anything more than that the Chicago people were good biologists and wanted some information on nonmammalian species of importance. However, we cannot be sure that the interest in fisheries in the Columbia River (chapter 11) did not provide a

stimulus in the highest managerial circles that was passed along in disguise to the Chicago workers.

Prosser et al. (1945) compared distribution after immersion of the fish in water containing the radioisotope with that after ingestion. They were comparable, indicating uptake through the gill and oral membranes. Calcareous tissues accumulated about 75% of radiostrontium and radiobarium with the rest residing early in soft tissues and being gradually transferred to bone. Lanthanum and a mixture of cerium, yttrium, and zirconium-columbium appeared to accumulate in visceral tissues, especially intestine. There was no fecal excretion of strontium after injection. Yolk of eggs in ripe ovaries took up some components of a fission product mixture, but not strontium or barium. The effect of age and calcium turnover appeared here as in mammals. Low calcium content of the surrounding water speeded uptake of ^{89}Sr and of fission product mixture.

Loss of the accumulated activity was quite slow when the fish were placed in inactive pond water.

Prosser, Hagen, and Grundhauser (1947) showed that solutions of stable barium, cerium, and bromine were toxic to goldfish at 1 ppm, 10 ppm, and 1,000 ppm, respectively, while strontium and iodine solutions seemed essentially nontoxic to goldfish. They also compared the lethality of x-irradiation, stable and radioactive elements in the alkaline-earth and rare-earth group but not in very much detail.

5. Enter the Dog and Some Comparisons

There was neither time nor space in the MED laboratories for the large and long-term dog experiments conducted in the postwar years (see later chapters). But the Chicago group did manage to inject a series of dogs with ^{89}Sr (and ^{239}Pu) as part of a much larger experiment using primarily external radiation. The initial published paper appeared in the Plutonium Project issue of *Radiology* (Vol. 49, No. 3) already cited. The paper, by Prosser et al. (1947), is something of a classic. Among other things, it shows in dogs and other large animals a faithful reproduction with the new radiation energies of the acute and subacute effects described as early as 1919 by Hall and Whipple (1919) and in Shields Warren's review (1942-1943) on the Pathology of Radiation (*Archives of Pathology*, Vols. 34, 35). The approach is considerably more physiological than in much of our more recent research.

The work with ^{89}Sr is mentioned briefly in the Prosser paper but in much more detail in a project report by Swift and Prosser (1947). Since this work has never been published in full form in the open literature (see NNES Hiatus, Appendix C), some details will be given here.

The injections were intramuscular, and the ^{89}Sr (with some ^{90}Sr contamination) from the Clinton Laboratories reactor was given in doses from 0.1 to 3.13 $\mu\text{Ci/g}$. The report does not give clear figures on the number of dogs used, but it was evidently enough for calculation of an LD_{50} .

The LD_{50} in 30 days was 1.0 $\mu\text{Ci/g}$ injected dose or 0.5 $\mu\text{Ci/g}$ retained dose. This is lower than reported for the rat and mouse by Anthony et al., or for the rabbit. Excretion was rapid in the mature dog^(a) as in rodents, with the bulk occurring in the first 3 days. After 10 days, excretion was quite slow. Therefore, the LD_{50} above based on retained dose might easily be based on retention after 10 days. But there was considerable variability in the longer-term retention with half-times from 1.6 to 37 days.

(a) Excretion was much slower and less complete in puppies and immature dogs.

As in the other species tested, deposition was primarily in bone. But the doses were high enough to produce acute damage before they were excreted, and the blood picture and general tissue pathology resembled, but did not duplicate completely, that seen after whole-body external radiation. The authors conclude that the initial dose is more important than the maintained dose. The main contrast in pathology to that of external radiation was the slower and less complete recovery of the leucocyte count due presumably to continued irradiation of bone marrow from the deposits in bone. There was not time for the development of long-term bone pathology. Nor was there time for a good analysis of long-term retention, but the data indicated power-function kinetics similar to those seen for radium (chapter 1).

The paper provides an opportunity for some interspecies comparisons with radiostrontium, as indicated in the tabular summary provided below:

Species	LD ₅₀ ³⁰ (Injected Dose Basis, $\mu\text{Ci/g}$)	LD ₅₀ ³⁰ (Retained Dose Basis, $\mu\text{Ci/g}$)	Excretion in 15 days, %
Mouse	7	2.8	60
Rat	5	2.5	50
Rabbit	5		90
Dog	1	0.5	58

The other reasons for the differences between dog and rodent obviously reside in factors other than retention and excretion.

This author has seen in abstract form a paper by Swift, Prosser, and Mika (1946) that presented a parallel study with ⁸⁹Sr in the goat. The rationale was to add a still larger mammal than the dog for extrapolation to humans and to check the tendency, suggested somewhat tentatively by the data shown above, that toxicity might increase with increasing body weight. The goat did not support this idea. The LD₅₀ in thirty days was in the range 1 to 1.5 $\mu\text{Ci/g}$, essentially the same as for the dog. Thus, a simple relation between acute toxicity and body weight did not materialize. In other respects, including response to whole-body x-irradiation, the goat resembled the dog. The decrease in lymphocyte count was noticeably less after ⁸⁹Sr in the goat than in the dog.

6. Chemistry and Radiocolloids

The enormous effort expended on establishing the chemistry, both physical and organic, of the fission products is quite beyond the scope of this book. A glimpse of the early processes is found in the letters quoted in the early parts of this chapter. The development of ion exchange resins was, of course, central to practical and large-scale separations. But the studies of metabolism were ringed by interest in how these elements attached to biomolecules and how their removal might be hastened.

Jack Schubert began such work at Chicago very early and has kept it as a career interest ever since. One of his early memos was seen through the courtesy of Dr. Hymer Friedell, and it gives the flavor of his advocacy for using exchange resins, either anion or cation, in preference to methods such as ultrafiltration, dialysis, and electrophoresis. In the memo, Schubert proposes a program for investigation of citrate and tartrate complexes of strontium and "at least one more rare earth" under physiological conditions. There were

undoubtedly many more such memos, but we will save discussion for the more extensive reports postwar.

These same avenues of investigation led Schubert to emphasize the radio-colloidal properties of fission products in solution (Schubert 1948). This is but a glimpse of a long-discussed and probably ubiquitous property of very dilute solutions that is especially notable with radiotracers. It can be characterized by diminished diffusion velocity, tendency not to pass membranes that are generally permeable to ions, adsorption upon glassware or walls of vessels, aggregation in solution, and even coagulation or peptization by electrolytes. Handling of solutions of radioisotopes at tracer levels can have a marked effect on the degree of colloid formation and undoubtedly has contributed in the past to many cases of nonreproducible results and effects attributed to "biological variability." We have already considered some of these phenomena in chapter 4.

Schubert's contribution in addition to presenting examples based on ultrafiltrability, ion exchange adsorption, and dialysis of carrier-free fission products of uranium is his characterization of radiocolloids and the very general role they play in tracer work whether in chemistry, physics, or biology. Note, for example, that a solution in radiocolloidal form may be distributed differently, at least initially, than an ionic solution because of the reaction of the RES to the "foreign object." The importance for nuclear medicine is obvious. This is highlighted in a paper by Gofman from Berkeley (1949). Further discussion will be reserved for later chapters.

C. The Chicago Toxicity Laboratory

The University of Chicago operated a toxicity laboratory during and after World War II which did numerous projects for the military.^(a)

The names of Kenneth DuBois, John Thompson, John Hutchins, and John Rust come immediately to mind as key members of the group. Their charge was largely chemical toxicology, and it ranged broadly. There was both official and unofficial liaison between this group and the MED and later ANL staff in the internal emitter field. Indeed, the Toxicity Laboratory was frequently studying the chemical toxicity of substances whose radioisotopes were under investigation at the Met Lab. Witness as one example the paper by Cochran et al. (1950) on acute toxicity of zirconium, columbium, strontium, lanthanum, cesium, tantalum, and yttrium.

D. Postlude at Chicago

While the end of World War II brought many changes to Chicago, the group most closely involved with work on fission products and actinide elements continued almost without missing a step. Indeed, several long-term experiments were already under way, which were fortunately carried forward pretty much as planned. Many of those in Met Lab administration returned to other duties, but, except for moving to the new facilities outside of Chicago, the progress of radioisotope research was relatively unbroken. It is tempting to launch into the extensions of fission product work immediately. But we need first to examine the MED work with the actinides and the genesis of the relative toxicity concept to make most efficient use of these later experiments and the philosophy behind them. Thus, further discussion will be postponed to chapter 8.

(a) Chemical Corps, U. S. Army for one.

V. Projects “Peppermint” and “Gabriel”

Early in the MED days, the MED and military planners were apprehensive that the Germans had learned the secrets of uranium fission, even if not the bomb, and might engage in air raids using radioactive isotopes as poisons. As early as September 15, 1942, J. C. Stearns wrote in a Met Lab monthly report on counter or defense measures including an elaborate selection of physicists at various educational institutions around the country who would be engaged to make radioactivity measurements in case of attack in their home locale (Stearns 1942). Note this was almost simultaneous with our first efforts to characterize the fission products from a biomedical point of view.

On a broader scale, selected military personnel in both the U.S. and U.K. forces were given radiation detection and measuring equipment and instructed in their use. Under the strictest kind of security, the fears of possible use of fission products for contamination of military or civilian installations were revealed to this relative handful of trusted individuals. Special shipments of the instruments were cached in various locations. Reports of any “epidemic disease of unknown etiology” were to be forwarded to specified officers with the plan that surveys for radioisotope contamination would be initiated thereupon. The same applied if unexpected darkening of photographic films appeared. Some of the instrument makers, e.g., Victoreen, developed and manufactured under high priority extra instruments to be placed in readiness. The Metallurgical Laboratory was a full partner, as well as the policy committee S-1 in Washington.

The American portion of this plan was code-named “Operation Peppermint” and was spearheaded by Major A. V. Peterson (1977) who writes about it in the Cave Brown-MacDonald book, *The Secret History of the Atomic Bomb* (1977).

While the American and British efforts were not officially combined, there was close liaison. Before the Normandy invasion, fears ran especially high that the Germans might be prepared to contaminate the beaches. Special efforts were made to inform General Eisenhower, and there were dry runs of Operation Peppermint by Headquarters, Chemical Warfare Service, European Theatre of Operations, U. S. Army.

None of this was very explicit about how biological doses would be estimated, etc. An effort to do this and to learn how to deal with such contamination was carried out, in part at least, at the University of Rochester Project. High-specific-activity short-lived radiosodium was sent by air from MIT to Rochester. It was applied to various surfaces in various configurations, and measurements were made. Then various procedures for removal were tried. From this, extrapolations were made to what the hazard might be had the emitter been mixed fission products. I am informed that this effort was named “Project Gabriel” (Bale 1979). It is likely that the above represents only a part of the effort.^(a)

(a) In addition to the probability of other measurements having been done elsewhere, there was one notable and quite unplanned result of this project. The ^{24}Na source prepared at MIT had an external radiation flux equivalent to about 5 g of ^{226}Ra . The rates were about 330 mr/hr at 1 m from the package. Such shipments usually went by military transportation. But there were problems in obtaining such at the time needed, and one of the commercial airlines agreed to carry it after briefing on where to stow it and how to handle it. Evidently all went well on the Boston-to-Syracuse leg of the trip, but because the box was to be off-loaded at the next stop, Rochester, it got moved to the forward compartment and very close to the pilot. On seeing the elaborate precautions taken by the University of Rochester crew when it was unloaded with

Neither of these involved sophisticated research. But they involved the same people and illustrate the variety of tasks that fell to the erstwhile laboratory scientists.

No evidence was ever found of the use of radioactive materials by the Germans, and the operations never needed to be activated. But they provided something of a prelude for later work at the Bikini and related tests in the Pacific. For the moment, we can put it beside the false alarm from thoriated toothpaste described in chapter 4.

VI. Work in Other U.S. Laboratories

We have concentrated on Berkeley and Chicago because, during the war, by far the bulk of true biomedical research on the fission products resided in these places. All of the installations handling fission products had to develop engineering controls and fairly elaborate systems for personnel protection and monitoring. Some of these efforts extended into possible environmental contamination and the effects of radioactive effluents on fish and wildlife and in agriculture. Notable among these was the work around the Hanford site, which will be discussed in chapter 11, along with later work at other production sites.

When the General Electric Company took over operation of the former Hanford Works, the biology operation began work on radioiodine. This had stood out as a biologically important potential contaminant from the large reactors and the separations plants. Details of the research results from this program and others will be taken up in chapter 8.

VII. Work in the United Kingdom

Cooperation with the British in sharing the scientific aspects of the development of nuclear energy has been amply documented. Near the end of the war, the Atomic Energy Research Establishment at Harwell could supply isotopes in the fission product series to medical researchers. Prominently interested in the biomedical implications was the group at Oxford, particularly Dame Janet M. Vaughan. (Dame Vaughan has continued actively in this field, especially with the bone seekers, ever since.)

Most of the publications are too late for the period covered by this chapter. But one which appeared in 1950 gives a vignette of their work. The study by Kidman, Tutt, and Vaughan (1950) was intended to determine the behavior of strontium as a function of diet and age in the rabbit. But the solutions of strontium isotopes contained varying proportions of ^{89}Sr , ^{90}Sr , and ^{90}Y . Thus, the radioactivity was constantly changing prior to and after injection. Yet, as stated

tongs, meters, etc., the pilot inquired into what it was. He was told enough to become thoroughly alarmed and insisted upon medical evaluation, for he had been, as he put it, "essentially sitting on that box!" This was July 6, 1943. Fortunately, it was a radioisotope that could be talked about without getting into classified areas; but why so much? The security people must have had some anxious moments.

It turned out that the pilot received less than 35 milliroentgens, and all medical examinations were negative. But this incident later played a prominent role in developing a guiding document for ICC regulations that were composed later with the help of a blue-ribbon committee of the National Research Council. (See Evans 1951.)

by the authors, "it seemed important, however, to obtain information about materials which are an immediate hazard, even though their estimation presented certain practical difficulties" (Kidman, Tutt, and Vaughan 1950, p. 210).

Despite the stated difficulties, the results agree well with those of the Hamilton et al. group at Berkeley and the work at Chicago: primary deposition in skeleton, rapid excretion initially, and difference in microdistribution of strontium and yttrium in bone. Excretion by both urinary and fecal routes was lower on a low-calcium diet than on a high-calcium diet. Uptake of strontium was always higher in animals on the low-calcium diet. Emphasized in the paper to a greater extent than in U.S. publications at the time is the hazard from the energetic ^{90}Y beta particles formed in bone from decay of ^{90}Sr .

VIII. Summary and Commentary

At the start of the Manhattan Project, the biomedical community faced an entirely new dimension in terms of the amounts of radioactivity to be expected if the uranium fission process worked. The total amount of radioactivity in all of the radium ever separated from its ores was but a tiny portion of that which could be expected in only a short time of operation of a nuclear reactor or from a fission bomb. Furthermore, hundreds of new isotopes could be expected. Fortunately, they were isomers of elements already known, but there were many unknowns, such as the fission yield, the many chains of radionuclides expected to be formed, and the like.

The new dimension was faced, even before the chain-reacting pile had been proven feasible. The cyclotrons at Berkeley (37 in. and 60 in.) could turn out fission products or mixtures in small quantities, and these were used early in the war years by Joseph G. Hamilton and his colleagues in tracer experiments with rats. The experiments were small, and the time between production of the radionuclides in the cyclotron and broad characterization of their behavior in the animal body was remarkably short. By the time fission products were available in quantity, their basic metabolic parameters had already been worked out. In addition to tracer work, the Berkeley group took time for some careful autoradiography, particularly of the bone seekers. They soon demonstrated significant differences in both micro- and macrodistributions among the elements produced in fission. There were those that behaved like calcium (e.g., strontium) and those that behaved like the rare earths.

There was also concern about those fission products that are gases or have gaseous phases in their decay scheme. A few crude experiments were tried, but the results will be reserved for discussion in chapters 9 and 10. There were also many calculations of possible lung dose from inhaled xenon and some interim standards set for airborne radioactivity in the installations of the MED.

At the Metallurgical Laboratory in Chicago, work with the fission products began slightly later than at Berkeley. As a result, they were able to secure amounts that permitted study of effects in small animals and of metabolism in large animals. The kinetics of retention and loss were emphasized. In addition, the fact that fission products could produce cancer, particularly in bone, as well as the entire galaxy of effects noted with acute external radiation doses became apparent. The initial carcinogenesis report is a classic, prepared by A. Brues, H. Lisco, and M. P. Finkel (1946).

There were also studies at Chicago on transfer of fission products from mother to offspring, considerable interest in the role of radiocolloids in

modifying or controlling behavior, including the contrast between carrier-free and ordinary fission products (J. Schubert and colleagues).

The fission products are, by and large, beta or beta-gamma emitters in contrast to the numerous alpha emitters we have dealt with in prior chapters. This is radiation of low linear energy transfer (LET) rate. As a result, the effectiveness per rad of deposited energy from the usual fission products is lower than that of radium, and there is a clear dose-rate effect. Thus, efficiency at low doses and low dose rates was found to be much lower than at high doses and high dose rates. Toward the end of the war, the Chicago group, especially M. P. Finkel, released data on the relative effectiveness of several fission products compared to radium. Under most circumstances, they were considerably less effective, but they became quite effective carcinogens at high doses and high dose rates.

Nearly all of the information on effects of fission products, during the war years, came from animal experiments. There were no exposures of humans, except for the rare accidental exposure and the early therapeutic trials of radio-nuclides like radioiodine. Only with the postwar exposures to fallout from weapons tests was there any appreciable exposure of either large groups of workers or the general population. These events will be discussed in chapter 12.

A part of the wartime effort on fission products was to prepare for the possibility of radiological warfare, e.g., by contamination of the landing areas for the invasion of Europe. After all, the fission process had been discovered in Germany. Why should they not be expected to pull a nasty surprise? Fortunately, the precautions taken were never needed, but the exercise has become part of the history we are reviewing.

In toto, the biomedical community was found ready for the new dimensions forced upon it by the enormous increase in amounts of radioactivity present or potentially releasable by the advent of nuclear fission. As in the decades before the war, it required development of new instrumentation and methodologies, and interaction of physics, chemistry, and biology. Only this time the barriers of security prevented the easy liaison of the 1930s. The biomedical community had to do much for itself under these circumstances, and it did.

Capsule Chronology

- 1940** Neptunium-239 identified at Berkeley (McMillan and Abelson).
- February 1941** Plutonium-238, then known as 94^{238} , isolated at Berkeley from products of neptunium decay (Seaborg et al.).
- August 25, 1942** Entire world's supply of plutonium spilled and recovered from soggy copy of the Chicago Tribune (Met Lab, Chicago).
- September 10, 1942** First weighing of pure plutonium and thus of any synthetic element (Met Lab, Chicago).
- 1943** Biomedical groups working on fission products. Little activity with actinides.
- January 1944** Recommended that Joe Hamilton (Berkeley) receive 10 mg of plutonium for metabolic studies.
Seaborg cautions of physiological hazards of plutonium and requests safety equipment.
- February 1944** Hamilton reports that gut absorption of plutonium is poor, retention predominantly in skeleton, excretion small.
- 1944** Curium is synthesized by Met Lab group (Seaborg, James, and Ghiorso).
Large Met Lab report on metabolism of plutonium in rats.
- 1944–1950** Large comparative toxicity and pathology experiment at Rochester (Boyd, Fink). Comparison of polonium, radium, and plutonium. Published in 1950.
- 1945** Americium synthesized by Met Lab group (Seaborg, James, Morgan, Ghiorso).
Work with plutonium in animals begins at Chicago using mouse, rat, and dog. First work aimed at determining effects as well as metabolism. (As with the fission products, the Berkeley work is largely at tracer levels.)
- 1945–1946** Eighteen patients injected with plutonium—California (3), Chicago (3), Oak Ridge (1) and Rochester (11). Metabolic studies show man similar to experimental animals. Patients reviewed in 1971–1972 (Durbin at Berkeley); public announcement not made until 1976 (AEC, ERDA).^(a)
- 1945–1949** Bioassay work booms at Los Alamos.
- 1946** Chicago work shows details of distribution and excretion of plutonium.
- 1946** Extensive study of acute and subacute clinical effects of plutonium in the dog (Painter et al. at Chicago).
Effects of plutonium on tissue metabolism (Barron at Chicago).
Carcinogenicity of plutonium to bone of rodents described (Brues et al. at Chicago).
Los Alamos begins limited animal program to back up bioassay work in man (Langham).

(a) For abbreviations and acronyms, see Appendix D.

- 1946-1948** Autoradiography work at Berkeley underlines both macro- and microdifferences in distribution of plutonium in bone compared to strontium, calcium, and radium.
- 1947** Large report from Berkeley on effects of diet, valence state, complexing agents, etc., on behavior of plutonium in vivo (Van Middlesworth).
- Large differences noted between plutonium and the fission products ^{89}Sr and ^{90}Y .
- Chicago emphasizes "The Liver Problem" with plutonium. Differences between results at Berkeley and Chicago noted and mechanisms tackled.
- M. Finkel (Chicago) studies transfer of plutonium from mother to offspring.
- M. Finkel (Chicago) expands long-term pathology and comparative toxicity experiment with mice.
- Histopathologic effects summarized by Bloom (Chicago).
- 1947-1948** Open literature publications of Berkeley work on plutonium, also transplutronics (Hamilton; Scott et al.).
- 1947 et seq.** Possible uses of plutonium and transplutronics as heat sources considered.
- 1949** Use of comparative toxicity data at Tri-Partite Conference (see chapter 16).
- 1949** Berkeley workers publish work on metabolism of ^{242}Cm (Scott et al.).
- 1950** Publication of "Langham Equation" for plutonium excretion by man. Much discussion of bioassay methods and results (Langham at Los Alamos).
- 1950** Publication of Rochester work with polonium, plutonium, and radium as a monograph in the National Nuclear Energy Series. (*Biological Studies with Polonium, Radium, and Plutonium* — Fink.)
- 1951** Some of the Chicago biomedical work on plutonium published in National Nuclear Energy Series (*Industrial Medicine on the Plutonium Project* — Stone).

Chapter 7

New Dimension Number Two— Plutonium and the Transplutonic Elements (the Actinides); 1940–1950

Overview

This chapter addresses the second “new dimension” facing the biomedical community, especially the Manhattan Engineer District (MED) medical section and the laboratories associated therewith. This second new dimension was, of course, the synthesis of plutonium and its production in large quantities and, to a lesser degree, the other actinide elements isolated later. The first new dimension, the fission products, was as much the expectation of enormously increased quantities as *de novo* encounters. There was at least background information on the chemistry and biochemistry of many of the elements in their stable form. With plutonium and related elements it was essentially a “start from scratch” on all aspects.

Four laboratories contributed the bulk of the information needed: the University of California at Berkeley and the University of Chicago groups working as part of the Metallurgical Laboratory and Plutonium Project; the project at the University of Rochester Medical Center, which operated under the MED but was not part of the Metallurgical Laboratory or the Plutonium Project; and the Los Alamos Scientific Laboratory, which entered the arena of biomedical research in the late war years.

Emphasis here is placed on the work done during World War II. Only when immediate postwar findings helped enormously to answer some burning question do we stray briefly beyond the war years. An exception is war work that was published postwar. As in previous chapters, we review some of the unpublished work in more detail than some others of equal merit.

Inhalation studies are reserved for chapter 9, bearing of the data on standard setting for chapter 16, and environmental aspects for the special series of chapters on environmental contamination (chapters 11–15).

It will be obvious that the discernment and foresight of a relative handful of individuals played a key role in seeing that this work was done and that it was applied to operations promptly and in depth.

It will be noted that only U.S. work is cited. For the period under scrutiny, plutonium and the higher actinides were essentially an American monopoly.

I. The Problem

The new dimension introduced by the fission products involved delineating the properties of a great variety of radioisotopes. Some of them were isotopes of well-known elements; others had been studied very little. But the presence of radioisotopes of these latter actually made investigation of their biomedical behavior considerably easier than when there were only small quantities of stable isotopes to be handled by chemical methods. While there was much newness, the chief concerns centered on the tremendous quantities to be expected. In contrast, the new dimension brought about by the synthetic actinide elements was completely a foray into the unknown.

The "discovery"^(a) of plutonium by the Berkeley group posed exploration of absolutely virgin territory in chemistry, physics, biology, and medicine. When the relatively easy fission of the isotope ^{239}Pu was demonstrated, and the decision was made to try to produce it in kilogram quantities, there was some of the same apprehension regarding health hazards as we saw with the fission products. Biomedical behavior needed to be known as soon as possible. Glenn Seaborg seems to have had more concern for biomedical problems than did many physical scientists of the day. Perhaps that is because he was a chemist. (Chemists get interested in biochemistry and thus in biology.) Perhaps he was nagged by Joe Hamilton, who had to stand by and see the Crocker Laboratory's 60-in. cyclotron and the machine at Washington University, St. Louis, grind away at producing enough plutonium to be weighed and its chemical properties determined at Chicago without getting a single microgram for biological study.

Seaborg put it this way in retrospect: "Up to the fall of 1943 the cyclotron-produced plutonium in existence amounted to only 2 mg, a quantity distributed throughout the program over a period of one and a half years—and a quantity so precious we could not afford to ingest any of it" (Seaborg 1970).^(b)

About the time the Clinton pile was ready to produce plutonium and the Hanford project was under construction, Seaborg sent the following letter, quoted by Langham and Healy (1973), to the Medical Director of the Plutonium Project, Dr. R. S. Stone:

R. S. Stone

G. T. Seaborg

(Declassified July 18, 1969)

Physiological Hazards of Working with Plutonium

It has occurred to me that the physiological hazards of working with plutonium and its compounds may be very great. Due to its alpha radiation and long life it may be that the permanent location in the body of even very small amounts, say one milligram or less, may be very harmful. The ingestion of such extraordinarily small amounts as some few tens of micrograms might be unpleasant, if it locates

(a) It was not really a "discovery," for plutonium was known to exist in 1941-1942, although not by that name (Seaborg 1980). It was a synthesis of a manmade element. In recent years, it has been decided that minute quantities of plutonium do exist and have existed in nature, the result probably of uranium fission by the ambient neutron flux. But in 1941, plutonium was completely new and completely synthetic.

(b) While there was certainly no carelessness, it might be remarked that even in those early days there were spills, and thus opportunities for ingestion or inhalation, e.g., a broken centrifuge tube that required wiping up a large fraction of the world's supply of plutonium from the floor, or, in another case, recovering a spill from the Sunday edition of the Chicago Tribune (Werner in Seaborg 1972; Perlman in Seaborg 1972).

itself in a permanent position. In the handling of the relatively large amounts soon to begin here and at Site Y, there are many conceivable methods by which amounts of this order might be taken in unless the greatest care is exercised.

In addition to helping to set up safety measures in handling so as to prevent the occurrence of such accidents, I would like to suggest that a program to trace the course of plutonium in the body be initiated as soon as possible. In my opinion such a program should have the very highest priority.

Central Reading File

(Seaborg 1944)

By January 19, 1944, it was recommended that 10 mg of plutonium for metabolic studies be made available to Dr. J. G. Hamilton "as soon as possible." By January 29, 11 mg of plutonium were allocated, shipped about February 1, and delivered to Dr. Hamilton on February 10. The Metallurgical Laboratory's monthly report for February (!) of that year (Allison 1944) carried the following from Dr. Hamilton:

Product Studies—Oral absorption of all valence states is less than 0.05%; lung retention high; absorbed material predominantly in the skeleton; excretion very small in urine and feces. (Langham and Healy 1973, p. 574)

This set the stage. The new element was biomedically similar to radium. The story of the radium dial workers, patients, chemists, and others had made a deep impression on Hamilton, on Seaborg, and on Stone. Laboratory modifications were instituted immediately, and the plant designs and working plans were adjusted to the philosophy that plutonium would be a very hazardous substance indeed.

Naturally, a full biomedical study was considered essential, and the Manhattan Engineer District (MED) faced up to the second major new dimension in its biomedical program. The work received added impetus as americium and curium were synthesized in 1946 and 1947, particularly since it was found that these were produced by successive neutron reactions in ^{239}Pu in the chain-reacting pile and in the products of some nuclear detonations. Thus, they would be present when fuel was reprocessed and in the debris from weapons. The quantities were far less than those of plutonium or fission products, but their very presence dictated more biomedical research.

The balance of this chapter considers, after a preliminary review of the actinide series of elements, the biomedical research done during World War II on these new elements, especially plutonium. The following chapter will tackle the enormous postwar research programs with both the fission products and the actinide elements.

II. The Actinide Elements

Just as we had to pause briefly in chapter 6 to review the production and properties of the fission products, we must pause here to review a few salient facts about the history and properties of the actinide elements.

The categorization "actinide elements" came out of the synthesis and properties of plutonium, neptunium, americium, curium, and later elements. Two

books by Seaborg present the essence of the story in clear-cut prose and fascinating style (Seaborg 1963, 1972). Full details can be found in some of the National Nuclear Energy Series (NNEs) and other volumes (Seaborg and Katz 1949; Seaborg, Katz, and Manning 1949) and in papers published along the way (Seaborg 1945, 1946.)

The search for transuranium elements in the late 1930s was based on the prewar periodic table (figure 7.1). Properties of the elements, when prepared, were expected to be like their nearest relatives in the table. For example, element 93 was expected to have properties like rhenium; 94 was expected to be like osmium, etc. This led to many unproductive investigations, complicated by the fact that in much of the early work the products of neutron bombardment of uranium were not transuranium elements at all, but fission products. The realization of this error came in the late thirties. With the establishment of the facts of uranium fission in 1939, the work took a different tack, and ^{239}Np ($^{239}_{93}\text{Np}$) was identified in 1940 in work at the 60-in. cyclotron in Berkeley. This was the first true transuranium element to be synthesized and characterized. Its properties were not at all like rhenium or technetium, even though they were in the same column of the old periodic table.

In late 1940, McMillan, Kennedy, Wahl, and Seaborg prepared another isotope of neptunium, ^{238}Np . This decayed by β^- emission to what appeared to be element 94, weight 238. On the night of February 23, 1941, the Berkeley group succeeded in separating the new element known then as 94^{238} and now as ^{238}Pu . Note that the first synthesis produced ^{238}Pu , not the more fissionable ^{239}Pu . The 239 isotope was searched for as a decay product of ^{239}Np . This was successful, again at the Crocker 60-in. cyclotron a little later, in the spring of 1941 (Seaborg et al. 1946). The first experiment with weighable (and barely visible) amounts of plutonium was carried out by Burriss Cunningham in collaboration with Michael Cefola and Louis Werner using the new and very clever techniques of ultra-microchemistry (Cunningham in Seaborg 1972). The fission cross section, fully

50% greater than the other most likely fissile material, ^{235}U , was established with slowed neutron beams from the 37-in. cyclotron. Again, the properties of the new element 94 were not at all like those of its relatives in the old periodic table, osmium or ruthenium.

Skipping a multitude of intermediate steps, in thought and deed, let it be said that Seaborg and the Berkeley group decided that these new elements belonged in a series analogous to the lanthanides, but one that began with actinium, and hence should be called "The Actinide Series." As the work progressed and larger quantities were available, the chemists at the Met Laboratory in Chicago (where Seaborg spent the war years)^(a) confirmed fully the progression of properties and predictions of behavior based on such a series. Thus, the elements we are interested in for this chapter became known as part of the actinide series of elements, or commonly the actinide elements.^(b) Analogies were drawn where appropriate, not to the old periodic table, but to the already established lanthanide series or rare earths. Soon the periodic table was rewritten by the Seaborg group as shown in figure 7.2.

FIGURE 7.2. Periodic table of the elements as it was rewritten by the Seaborg group in the 1940s to show the new actinide series. (Redrawn from Seaborg 1963, p. 41. Reprinted with permission of Prentice-Hall, Inc., Englewood Cliffs, New Jersey, copyright 1963.)

The synthesis and isolation of americium and curium came at the wartime Metallurgical Laboratory in Chicago after the big push to develop the methods for isolation and extraction of plutonium on an industrial scale was over. A. Ghiorso, R. A. James, L. O. Morgan, and G. T. Seaborg were involved in this

(a) Seaborg 1980.

(b) The early members, including thorium and uranium, although officially part of the series, are not so commonly identified as "actinides," and we have considered these separately in earlier chapters of this book because of their natural occurrence in quantity.

work. For curium, the cyclotron at Berkeley did the bombarding, while the chemical separations went on at Chicago. Curium-242 was separated in the summer of 1944 after bombardment of ^{239}Pu with 32-MeV helium ions. Americium-241 was isolated at Chicago in 1945 after bombardment of ^{239}Pu with neutrons in a reactor. Both of these elements fitted well the scheme of the actinide series. As Seaborg remarked, "...the actinide concept had crystallized" (Seaborg 1972, p. 57). (See also Seaborg 1949a,b; Seaborg, Katz, and Manning 1949; Seaborg, James, and Morgan 1949; Seaborg, James, and Ghiorso 1949.)

The actinide concept was not only useful to the chemists; it was useful also to the biochemists and biologists in working out the metabolic behavior of this group of elements. The literature is voluminous, but the writings of David Taylor (Royal Cancer Hospital, Sutton, Surrey, Great Britain, now at the Karlsruhe Institute in Germany) are especially useful in depicting the chemical properties of importance to biological behavior of both plutonium and the transplutonium elements (Taylor 1973a,b).

All of the actinides above actinium are radioactive, except that thorium and uranium in their natural state are quite weakly radioactive (chapters 2 and 4). For our purposes, it is primarily the deposition of energy from ionizing radiations (alpha, beta, and/or gamma) that governs the biological effects of importance for the higher actinides, although some component of chemical toxicity cannot be ruled out completely.

III. The Metabolism of Plutonium

A. Radiochemical Studies In Animals

The Metallurgical Laboratory's monthly report for the period ending October 15, 1944 (Hamilton 1944)^(a) discusses in some detail the facts from Berkeley in the cryptic announcement made in February. Organ distribution and retention in rats are given at four, sixteen, and sixty-four days following oral, intramuscular, intravenous, subcutaneous, and intrapulmonary administration. The doses were 15 μ (15 μg) per animal, with three rats in each group, the same protocol as in the research with fission products.

The skeleton is emphasized as the chief organ of deposition and the digestive tract the principal channel of excretion. Retention in the skeleton was tenacious, with the half-period estimated at over six months.

Absorption in the gastrointestinal tract was about 0.05%, considerably less than the absorption of radium. Valence state played an important role in absorption. More complete information is found in a large Met Lab in-house report (Scott et al. 1944) which appeared, in part, in the *Journal of Biological Chemistry* (Scott et al. 1948a).

Liver had the highest concentration among the soft tissues. There was a marked effect of valence state. Deposition in liver after intravenous administration was greatest for +4 plutonium, intermediate for +3 plutonium, and least for the +6 state. This was essentially the reverse of the effect of valence state on

(a) The plutonium used at Berkeley for biomedical work did not come from the 60-in. cyclotron, which produced relatively small amounts of the ^{239}Pu isotope. Instead, Berkeley, like Chicago, Los Alamos, and Rochester, used ^{239}Pu produced in a nuclear reactor, at first the Clinton Laboratory reactor (Oak Ridge).

absorption from the gut. The liver was not so high after administration by other routes. Kidney and spleen were the next highest among the soft tissues.

Even in the early studies, there was considerable interest in finding mechanisms to explain the kinetics found. Lester Van Middlesworth prepared a Ph.D. thesis, subsequently issued as a Manhattan District declassified report (Van Middlesworth 1947) that brought many influences to bear, such as diet, valence state, complexing agents, etc. Some of the most pertinent findings are outlined below and in figure 7.3.

FIGURE 7.3. Effect of valence state on disappearance of plutonium from the blood of rats following intravenous administration. (Redrawn from Van Middlesworth 1947.)

1. By a clever selection of radiation types and energies, the behavior of ^{239}Pu , ^{89}Sr , and ^{88}Y could be distinguished in the same animal (in this case rats).
2. Severe phosphate deficiency greatly reduced the retention of strontium. The retention of plutonium was somewhat reduced, but tissue distribution remained the same.
3. Excretion patterns of the three elements were quite different, although all three reached a very low rate within a few days after injection. Urinary excretion of plutonium was very slow after the first week, so that less than 4% of the administered dose appeared in urine over an eleven-week period. Fecal excretion was much higher and continued to be quite significant over the eleven weeks (cumulative about 25% of administered dose). In fact, the rate of excretion of plutonium in feces, while initially lower than the rate with either strontium or yttrium, exceeded either of these after the fifth week.
4. Scurvy, which produces changes in connective tissue and bone osteoid matrix, had no significant effect on the distribution of plutonium.
5. The tissue distribution of plutonium was not altered by three weeks of a protein-free diet, although retention at the injection site was reduced.
6. The valence state +4 ($\text{Pu}(\text{IV})$) was retained at a site of intramuscular injection longer than the +6 state ($\text{Pu}(\text{VI})$). Distribution was unchanged.

7. Valence state had a marked effect on disappearance from the blood (figure 7.3). It was postulated that this difference, plus the much larger proportion of the +4 state depositing in liver, confirmed the idea that the (Pu[IV]) may be in a colloidal state.
8. Maximum uptake of plutonium (and yttrium) in a fracture callus occurred on the second or third day, whereas strontium deposition did not begin until the period of most active calcification.
9. Methionine supplements in the diet produced a moderate decrease in deposition of plutonium in the skeleton when it was injected in the valence VI state, whereas large doses of cysteine injected one hour before intramuscular injection had no effect on absorption of (Pu[IV]) but reduced both absorption and skeletal deposition of (Pu[VI]).

All of these findings bear on a primary problem that was in the minds of the early workers and continued well into the postwar years. What is the chemical form of plutonium in tissues and excreta? Can the knowledge of the chemistry aid in deriving means for therapeutic removal of plutonium? We will return to these questions.

Let us turn first, however, to the published summaries of the Berkeley work already cited in connection with the fission products (Hamilton 1947, 1948). Figure 7.4, taken from Hamilton's 1947 paper, shows the uptake and retention in bone of several actinides, including plutonium, following parenteral administration. Note the almost negligible loss from bone over a period of sixty-four days and contrast this with the fission products discussed in chapter 6, where loss, while slow, was clearly at least measurable, except for element 61 (figure 6.2).

FIGURE 7.4. Uptake and retention of actinide-type elements by bone of rats. (Redrawn from Hamilton 1947. Reprinted with permission of Radiological Society of North America, Oak Brook, Illinois, copyright 1947.)

Figure 7.5, also from the Hamilton review, shows uptake and retention of these same actinides by liver. The contrast in retention between bone and liver is even more marked than in the case of the fission products. The difference is due largely to the avid retention in bone.

FIGURE 7.5. Uptake and retention of actinide-type elements in liver of rats. (Redrawn from Hamilton 1947. Reprinted with permission of Radiological Society of North America, Oak Brook, Illinois, copyright 1947.)

Work at Chicago on the metabolism of plutonium followed much more closely on the heels of the work at Berkeley than was the case for the fission products. One of the earlier reports concerned metabolism in and effects on a dog (Cole and Prosser 1945). The injection was intravenous. The findings were similar to those reported from Berkeley in the rat, but, in addition, combination of product (plutonium) with blood plasma proteins was described along with mention of high concentrations in lymph nodes and high specific activity in spleen. The plutonium was given in the +6 valence state.

In the same report (and without any indication in the table of contents), some metabolism figures are also given for mice. Besides the now familiar findings, they took autoradiographs of the liver of mice treated intraperitoneally and found very little of the product on the outer linings. This fact was taken as proof that the liver deposition was from complexes in blood plasma.

Another in-house report from Chicago appeared as part of a conference on plutonium held May 14-15, 1945 and issued as a Met Laboratory report on July 23, 1945 (Nickson 1945). A paper by R. D. Finkle in that volume gives summary data on the dog and mouse using plutonyl (+6) nitrate by intravenous, intraperitoneal, and intramuscular routes of injection but without much analysis of the findings.

By far the most complete in-house report from Chicago was issued in May 1947 (though dated August 1946) with contributions from most of those concerned with the metabolic studies (R. D. Finkle et al. 1947). This report was

scheduled for publication as a detailed paper in the *Plutonium Project Record* (PPR), later the NNES, Volume 22G, which did not get published (See NNES Hiatus, Appendix C). Because of its summary nature and the presence of constant demand, it was reworked by Francis E. Throw, editor for the Radiological and Environmental Research Division, Argonne National Laboratory and reissued in March 1976. The chapter on metabolism was prepared by Snyder, Kisielewski, and R. D. Finkle. The abstract is presented below.

Abstract. The most important aspect of plutonium metabolism is the affinity shown by the bone to capture the material and hold it for a long time. From data on rats that received plutonyl citrate and those that received plutonyl nitrate, it was estimated that the half-time for the plutonium in the skeleton was roughly 1.5 yr. With rats and mice, over 50% of the administered (intravenous) plutonium was deposited in the skeleton.

At 200 days, deposition in the rat skeleton averaged 10% of the retained dose per gram of bone ash. Somewhat higher concentrations were found in the lumbar and thoracic sections of the spine, while lower concentrations were found in the skull, jawbones, and ribs.

The next largest deposit of plutonium was in the liver (20 to 40%). This organ did not hold the material; the concentration was reduced to approximately one-tenth of the initial value within 200 days. In mice, part of the plutonium that left the liver found its way to the skeleton; but in rats no evidence of such a relocation was observed. The removal from the liver offered that the first step is a conversion of the plutonium from one molecular form to another form, more easily removable from the liver. The suggestion that the collection of a large fraction of the plutonium by the liver is an abnormality associated with intravenous administration was not supported by the evidence presented. Intramuscular and intraperitoneal administration of plutonyl salts also produced high plutonium concentrations in the liver.

Intramuscular injection of plutonyl nitrate in mice resulted in slow absorption: 23% was absorbed in 4 days, and 46% in 64 days. Of the absorbed portion, 20% was found in the liver initially.

Rats that received plutonyl salts by vein excreted 17% of the dose in the first two weeks and another 10% in the next six weeks. Over this eight-week period, the feces contained three times as much plutonium as did the urine. The rate of excretion on the eighth week was 0.08%/day. Mice that received similar treatment excreted 12% in the first two weeks and another 12% in the next eight weeks. The rate of excretion in the tenth week was 0.07%/day.

(R. D. Finkle et al. 1947)

Note that the estimate for half-time in the skeleton has slipped up to 1.5 yr. Note also differences in the concentrations in different bones, not emphasized in the earlier reports. The analytical methods are carefully described. Recoveries were good for most tissues and feces, but poor for urine because of problems with spattering in the dry-ashing procedure, and also for overall recovery when much time elapsed between injection and termination of the experiment. The figures were $97\% \pm 3\%$ for soft tissues, $94\% \pm 3\%$ for feces, 75% for urine and 88% for overall recovery with a range from 70% to 100%. These low overall recoveries were attributed to plating out of plutonium from urine and feces on the metal metabolism cages.

Excretion was fairly regular except in the mouse, where it was quite variable. A picture of the general trend of excretion is shown in figure 7.6, taken from the subject report.

Note that the bulk of the excretion occurs in the rat in the first few days with not over 2% being excreted in the three- to fifty-day period. Urinary excretion

FIGURE 7.6. Mean accumulated excretion of plutonium in urine and feces of rats after parenteral administration. (Redrawn from Finkle et al. 1947.)

appears to go to zero after five to eight days, but is actually about 0.01% to 0.02%/day. The importance of this for bioassay procedures is obvious if the same applies to man (see chapter 16). Fecal excretion remained significant for at least forty days.

There are some contrasts in detail between these excretion figures and those of Van Middlesworth (1947), which are shown along with data for strontium and yttrium in figure 7.7.

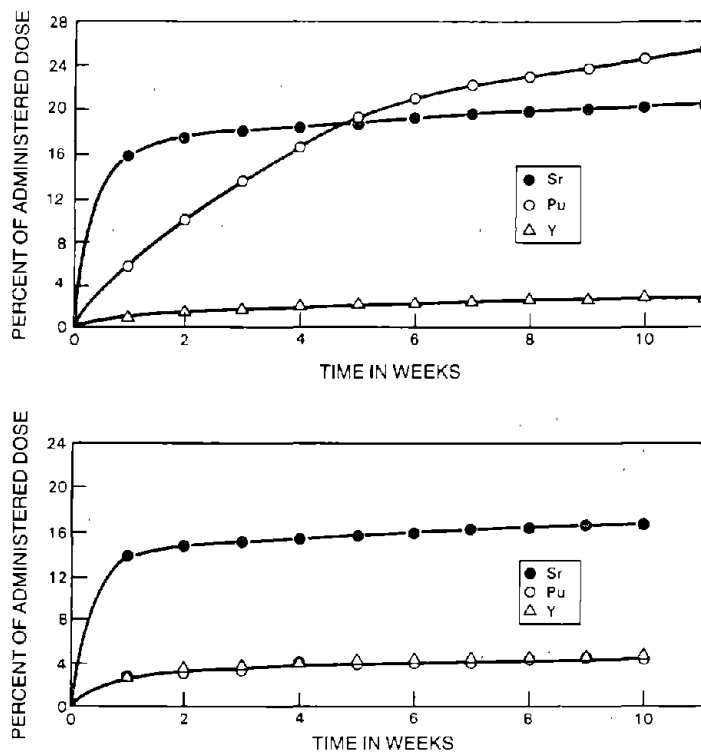

FIGURE 7.7. Cumulative excretion of plutonium, radiostrontium, and yttrium after parenteral administration (urine [A]; feces [B]). (Redrawn from Van Middlesworth 1947.)

The Chicago workers were especially impressed by the deposition in liver under various conditions. In the report by R. D. Finkle et al. (1947) there is a section called "The Liver Problem." They considered as a mechanism entrapment of colloidal material, even precipitated plutonium, brought about by rapid intravenous injection. Influence of valence state also suggested this since the more insoluble +4 valence state was "the worst offender." Would this apply to slow absorption from lung or wound site in man? Would the amount in liver be significant in man? Specific animal experiments were designed to investigate "the liver problem." It turned out that the route of administration was not a prime factor in determining liver deposition. Even attempts to obtain low liver content after intravenous administration by using the citrate complex, great care to remove foreign matter such as lint and dust from the injection solution, and use of highly acidic stock all failed to remove "the problem." Always the initial liver content exceeded 20% of the injected dose. As we will see later, the story is no different for humans.

The Berkeley group consistently got much less in liver than the Chicago workers. Two possible explanations were: (1) the amounts used by the Chicago group were much larger because they were interested in toxicity; and (2) while initially both laboratories used the same source of plutonium, in later work the sources were different.^(a)

The Chicago report concludes its discussion of "The Liver Problem" by pointing out a striking similarity in four of the larger intravenous experiments, where each curve seems to be composed of two separate lines in the plot of percent dose against time. This is reproduced here as figure 7.8. They argue that the rather sudden increase in release of plutonium from the liver represents the culmination of solubilization processes, probably several, and subsequent mobilization. Analyses of the plutonium content of the blood showed a rise at about the time of the inflection in the rate of loss from liver. Interestingly enough, rats receiving plutonium in the lungs failed to show the increase in rate of loss from liver at ten to twenty days. Many attempts were made to find what changes were occurring in the chemical state of plutonium in the liver, but,

FIGURE 7.8. Retention of plutonium in various forms in the liver of rats and mice. (It is postulated that the portions marked "A" correspond to the period during which plutonium is being converted from the chemical form in which it is deposited to a more mobile form; part "B" is taken to show removal rates of this more transportable form of plutonium.) (Redrawn from Finkle et al. 1947.)

(a) The report indicates that this point is discussed further in another PPR report. But only an abstract has been obtained of this, which does not address the subject, although it points out the importance of the rate of injection.

except for finding that all of the intravenously injected plutonium was associated with protein, no specific explanation was forthcoming. Muntz and Barron (1947) had already implicated one of the heavier serum proteins.

It is puzzling that this phenomenon (i.e., a change in mobility) has not, so far as this author can find, been followed up in postwar work. It might be pertinent to means for therapeutic removal.^(a)

M. P. Finkel's work (1947) on transfer of radioelements from mother to offspring in laboratory animals, already discussed in chapter 6, was extended also to plutonium. Very little plutonium seemed to cross the placenta, in line with its general tendency toward insolubility. But, as with ^{89}Sr , the plutonium-treated mothers lived longer than the nonpregnant animals. Possibly enough plutonium leaves the mother via the milk to reduce her body burden. While the young at birth retained only a small portion of the plutonium in the mother, the young from mothers receiving ^{89}Sr had activities above those in the mother.

The newborn appeared to absorb much more plutonium from the gut than do adults—in line with findings with other substances. This was not sufficient, however, to bring about pathologic lesions over the period of the experiment as occurred with radiostrontium. Thus, the hazard of plutonium by placental transfer, or milk from lactating mothers, appears less marked than with fission products, despite the much higher biological effectiveness of the plutonium alpha particle. The mice in utero were kept for length-of-life studies, but no osteosarcomas appeared. This phenomenon deserves further investigation since, as we will see presently, plutonium is in general more effective at low doses than is strontium.

The effect of valence state on disappearance of plutonium from the blood, noted earlier in the work of Van Middlesworth (1947) at Berkeley, was also noted in the Chicago work along with the fact that complexing with citrate did not alter the metabolism of either plutonium or yttrium (Schubert et al. 1950).

Kisieleski and Woodruff (1947) looked at the effect of valence on absorption after intramuscular, subcutaneous, and intrapulmonary routes. The effect described was similar to that noted earlier when other routes of entry were utilized.

The Los Alamos Scientific Laboratory was, of course, a mecca for work in the physics and chemistry of plutonium. During the war years, its biomedical program was centered largely around the health care of the workers there and ways to estimate body content from measurement of excretion (bioassay). We will discuss this in more detail in chapter 16. The laboratory did not have facilities for a biomedical program with animals until toward the end of the war in Europe. Wright Langham, who was a central figure in the bioassay work, did persuade management to let him do some experimental work with rats, primarily aimed at checking out excretion phenomena that had not been explained and some tissue distribution work. This work was reported in May 1946 as a Los Alamos report and later issued as an Atomic Energy Commission (AEC) declassified report (Langham 1946). It gives a summary of much of the Berkeley and Chicago work as well as their new data. Parts were published in 1947 (Carritt et al. 1947).

(a) The "liver problem" per se has not disappeared. There are indications from many sources, including the Thorotrast work described in chapter 4, that liver damage may be significant under some conditions, and it cannot be neglected.

The new work emphasized further the growing suspicion that extrapolation from the rat to man is especially shaky in the area of bioassay.

Langham's work shows what may be an effect of dose size on the ratio of fecal to urinary excretion (F/U). At least table 5 of his paper shows a progressive increase at five days from an F/U ratio of 4.93 to 8.09 with increasing dose from 1.1 γ (μ g) to 15.0 γ . But at 52 γ , the ratio was back to 5.45. None of these may have application to the much lower doses involved in radiation protection work. Also, by thirty days the ratio seems to be quite constant (Carritt et al. 1947):

A key conclusion was that, regardless of valence state, distribution of plutonium slowly absorbed into the body by oral, intramuscular, or intrapulmonary routes was similar to that following intravenous injection.

Comment: These radiochemical studies during the war years at Berkeley, Chicago, and Los Alamos established the main features of plutonium metabolism in animals. While there were differences, the similarities in primary findings are striking, especially if it is remembered that security measures interfered with easy communication, and the methodologies were idiosyncratic.

Toward the end of the war years and immediately thereafter, there were publications showing the metabolism of americium (Scott et al. 1948b) and of curium (Scott, Axelrod, and Hamilton 1949). These fell clearly within the actinide group of elements in terms of general behavior, but there were differences between them and plutonium. We will reserve discussion of these for chapter 8.

B. Autoradiographic Studies

It is not clear whether the autoradiographic studies at Berkeley involving plutonium were simultaneous with or somewhat later than the work on fission products described in chapter 6. But the fact that microdistribution of plutonium was very different from that of radium rapidly became a central issue in guiding standard-setting.

Figure 7.9 is a combination photomicrograph and autoradiograph of an adult rat femur seventy days after injection of ^{226}Ra (Durbin 1976). The distribution in the mineral phase is much like that shown in chapter 6 for radiostrontium.

FIGURE 7.9. Photomicrograph (left) and autoradiograph (right) of an adult rat femur seventy days after injection of ^{226}Ra . Note the similarity of the radium deposition (autoradiograph) to the mineral phase seen in the photomicrograph. (Unpublished figure from Durbin 1976.)

In figures 7.10 and 7.11, we see photomicrographs and autoradiographs of adult rat femurs one week and eight weeks, respectively, after injection of plutonium (presumably ^{239}Pu).

FIGURE 7.10. Photomicrograph (left) and autoradiograph (right) of femur from adult rat injected with plutonium and sacrificed one week later (note the superficial distribution of plutonium). (From Hamilton 1947. Reprinted with permission of Radiobiological Society of North America, Oak Brook, Illinois, copyright 1947.)

The difference between plutonium and radium is striking, as is the similarity between plutonium and some of the rare earths (Hamilton 1947). These autoradiographic studies led to the postulate that plutonium combined with the organic matrix of bone, while radium entered the mineral crystals (hydroxyapatite) by exchange for calcium. It became an important bench mark for explaining the differences in toxicity to be discussed later in this chapter. Van Middlesworth (1947) emphasizes the difference between strontium and plutonium (strontium being like radium as we saw in chapter 6). He attributes the localization of plutonium to deposition on the endosteal and periosteal surfaces—a more correct explanation than simply “binding with organic matrix.”

FIGURE 7.11. Similar to figure 7.10 but eight weeks after injection. (From Hamilton 1947. Reprinted with permission of Radiobiological Society of North America, Oak Brook, Illinois, copyright 1947.)

C. Metabolism of Plutonium in Man

The fact that thousands of MED workers would be handling plutonium, some of the conflicting information arising from the animal experiments, and the usual problem of applying data from animals to important quantitative figures needed for humans, generated a very strong desire to have direct information from man. Therefore, a program was begun in which selected hospital patients were given what were then regarded as tracer-level doses of soluble plutonium. Body excretions were collected. Since most of the patients were selected because they had a short life expectancy, some died moderately soon, and tissue samples were analyzed as were excreta. Others lived for many years, even long enough to cast doubt on the validity of the original medical opinion or to confirm the resiliency of the human organism.

Between April 1945 and July 1947, a total of eighteen patients received injections of soluble plutonium. Some were in "metabolism wards" of their respective hospitals where they were in-patients for disorders already requiring collection of excreta, measuring of food and fluid intake, etc. Three of them were at Billings Hospital of the University of Chicago, one was at the MED Hospital at Oak Ridge, eleven were at Strong Memorial Hospital of the University of Rochester, and three were at University Hospital at the University

of California, San Francisco. Those at Rochester and Chicago were in metabolism wards, the others in no special facility.

The first report came from California (Crowley et al. 1946) and was undoubtedly a stimulus to do further work since the metabolism in humans appeared to be rather different from what had been seen in the rat. While prolonged retention and selective deposition in the skeleton were common to both species, the elimination was at a higher rate in the rat to the tune of 50% of the administered dose against 5% for humans in an unstated period. Also, elimination in the rat was primarily via the feces, whereas the major elimination in humans seemed to be via the urine.

The first cases contributing the data on man were either the ones designated Cal-1 and Cal-2^(a) injected on May 14, 1945, and April 26, 1946, respectively, or Ca1-1 and Chi-1. Since the cited report by Crowley et al. is dated May 31, 1946, it is doubtful if Cal-2 could have contributed very much information. Besides, this was a very ill, four-year-old child with bone cancer. But an important conference held in May 1945 mentions two cases. Since there was one done at Chicago in April 1945, it is possible that they considered these two adults—one from California and one from Chicago.

The cases done at Rochester, designated HP-1 through HP-11, were strictly a cooperative operation between the Los Alamos Scientific Laboratory and the Rochester Project. Wright Langham came to Rochester to supervise the handling of the plutonium and general planning. Most of the radiochemical analyses were done at Los Alamos. It is not clear by what means the samples traveled from Rochester to Los Alamos, and they were plentiful as anyone who has ever been associated with such work knows well. In view of the security surrounding all plutonium operations, they may have been escorted, probably by Dr. Langham himself on a train. Rochester contributed the medical team of the Metabolism Ward and scientific collaboration from members of the MED project. The report, which is now a classic, was not issued until 1950. The authors were Wright Langham, Samuel Bassett, Payne S. Harris, and Robert E. Carter (1950), and acknowledgments were made to fifteen staff members of the two institutions. The report also states that Stafford L. Warren, medical director of the MED, was primarily responsible for initiation of the work. While the report was issued as a joint report of Los Alamos and Rochester, it bore a Los Alamos report number, and there was not much overt attempt to identify the institutional connections of the many workers. Thus, it remained somewhat mysterious except to those who had direct connection with it. This was aided by keeping it classified "Secret" for many years, then "Restricted," then "Official Use Only" since some of the patients were still alive, and at long last "unclassified." The latter action came in time to allow this report, carrying as it does many of the graphs and interpretations used for years in bioassay work on plutonium, to be included as a "landmark paper" in the special silver anniversary issue of the journal *Health Physics* in 1980. The authors include results not only from the HP patients but Cal-1, Chi-1, and Chi-2, and urinary plutonium assays from a few Los Alamos workers. The cases Chi-1 and Chi-2 were described also by Russell and Nickson (1946).

(a) It was the mountains of dirty glassware from Cal patients that started Patricia Durbin, then Patricia Wallace, in the position of "diener" at the Crocker Laboratory. Now we are indebted to her, among other things, for a complete and sophisticated review of all the human injection cases (Durbin 1971, 1972). Included for the first time is full information on Cal-2 and Cal-3.

A summary of the designation, date of injection, and other pertinent information for all eighteen patients is given in table 7.1, modified from an Energy Research and Development Agency (ERDA) press release dated February 1976.

TABLE 7.1. Summary Of Plutonium Injection Patients

Case	Age	Patient Data		Diagnosis	Injection	
		Sex	Race		Date	Place
Cal-1	58	M	W	Stomach Cancer (misdiagnosis)	5/14/45	California
Cal-2	4	M	W	Bone Cancer	4/26/46	California
Cal-3	36	M	B	Bone Cancer	7/18/47	California
Chi-1	68	M	W	Cancer of Mouth	4/26/45	Chicago
Chi-2	55	F	W	Breast Cancer	12/27/45	Chicago
Chi-3	Young adult	M	W	Hodgkins Disease	12/27/45	Chicago
HP-1	67	M	W	Duodenal Ulcer	10/16/45	Rochester
HP-2	49	M	W	Hemophilia, Heart Disease	10/23/45	Rochester
HP-3	49	F	W	Hepatitis, Hypoproteinemia	11/27/45	Rochester
HP-4	18	F	W	Cushing's Syndrome	11/27/45	Rochester
HP-5	56	M	W	A. L. Sclerosis	11/30/45	Rochester
HP-6	45	M	W	Addison's Disease	2/01/46	Rochester
HP-7	59	F	W	Rheumatic Heart Disease	2/08/46	Rochester
HP-8	41	F	W	Scleroderma	3/09/46	Rochester
HP-9	66	M	W	Dermatomyositis	4/03/46	Rochester
HP-10	52	M	B	Rheumatic Heart Disease	7/16/46	Rochester
HP-11	68	M	W	Cirrhosis of Liver	2/20/46	Rochester
HP-12	53	M	B	Severe Auto Accident Injuries	4/10/45	Oak Ridge

Source: Modified from an ERDA press release, February 1976.

Excretion measurements were obtained in the initial work as follows:

HP-1	24 days	HP-9	35 days
HP-2	27 days	HP-10	30 days
HP-3	23 days	HP-12	38 days plus 43 to 46 days
HP-4	23 days plus 79 to 82 days	Chi-1	to 138 days with a few breaks
HP-5	22 days	Chi-2	to 138 days with several breaks
HP-6	22 days	Chi-3	16 days
HP-7	28 days plus 79 to 85 days	Cal-1	to 138 days.
HP-8	64 days		

In addition, HP-6 provided four consecutive daily urine samples beginning at day 523 and another set beginning at day 1,610. HP-3 contributed four samples beginning on day 1,645.

Blood contents were measured in all twelve HP patients. Tissue samples were obtained and analyzed from HP-5, HP-9, HP-11, Chi-1, Chi-2, and Cal-1. A few samples were obtained also from HP-12.

The composite results of this rather large effort left no doubt that the experiment was essential to proper use of metabolism data to establish protection procedures for workers—and indeed for the general population. Even though the tissue samples were small, and the patients quite ill before their deaths, conclusions could be drawn:

1. There were no *major* differences in tissue contents between humans and the common laboratory animals with the exception of liver.
2. The amount in the liver of humans may be 20% to 40% versus 10% or less for rats receiving the same Pu +4 citrate complex.
3. The retention half-time in liver is greater in humans.
4. The retention half-time for total body in humans is estimated at 118 yr (range 84 to 175), much longer than in laboratory animals.
5. The excretion pattern is clearly different, as will be discussed below.

The urinary and fecal excretion for the 138 days of collections on the patients in this study is shown in figure 7.12. Also shown are mathematical expressions derived by the authors depicting the excretion as a power function of time. Note that in the early times fecal excretion exceeded urinary, as in the animals,

FIGURE 7.12. Excretion of plutonium by patients described in the text. The Y axis represents a rate % of injected dose excreted per day. In the derived expressions, Y = percentage of injected dose excreted each day, X = the time postinjection, and the subscripts refer to urine (u), feces (f) and urine and feces (u+f). (Redrawn from Langham et al. 1950.)

but after about 30 days the urinary component was the larger, quite different from the rat. (These were intravenous injections. Hence, the elimination of unabsorbed plutonium in the feces in the early period is not a complication as it would be for oral or inhalation exposures.) The original paper gives the complete data on each subject, the derivation of the expressions given, and much additional information.

The needs of a substantial bioassay program built on excretion measurements could not be met with data up to only 138 days. Therefore, Langham introduced an extrapolation based on excretion by workers at Los Alamos. Here the amounts were very small, and there was no independent measure of the amount of plutonium in the body. Thus, there is greater uncertainty than in the period up to 138 days. However, something was known about the exposures from the monitoring procedures. By translating a chronic variable exposure dose into an effective single dose between the limits of exposure at some effective time, some additional points could be added. An adjusted excretion expression was thus obtained:

$$Y_{ua} = 0.20X^{-0.74}$$

where Y_{ua} = adjusted urinary excretion rate and X is time. To do this, they assumed the excretion beyond 138 days was exponential to time and made estimates of an absolute minimum value for biological half-time.

The results, carried to 1,750 days, i.e., about five years, are shown in figure 7.13. Integration of this expression shows that even through 1,750 days urinary excretion accounted for only 6.3% of the total injected dose.

The demands of an assay program based upon such a small fractional excretion rate per day are obviously very great. Yet, these data and these curves formed the basis for practice in the MED and later in the AEC, although some modifications were introduced. The equation has been known as the Langham equation. While these graphs appeared in many postwar summary publications, they were without the details of derivation. It is primarily in the report LA-1151 that the whole story is shown. Since the paper has now at long last reached the open literature in the special issue of *Health Physics* (1980), its perusal by all interested is heartily recommended. There will be further discussion in chapter 16, including the results of re-examination in the light of postwar work. But, for the present, the work stands as a monument to what the MED people could do with less than ideal material to work with.

Comment: The fortuitous circumstance that four of the patients, three at Rochester and one in California, were still living in 1976, more than twenty years after injection, and that HP-1 lived fourteen years to age eighty-two, none of them showing any gross effects of the plutonium injection, lends credence to the view that the injections produced no measurable harm. Obviously, the group is so small that no statistical validity can be attached to this statement, nor can it be assumed that had the whole group lived more than twenty years no untoward effects would have been seen. Yet, these facts raise questions about the now popular slogan that "plutonium is the most toxic element known to man." We will return to this in a following section.

In chapter 2, we commented on the importance of the planned administration of uranium in man. The importance of the information gained from the planned administration of plutonium is at least an order of magnitude greater. Protection of all the workers in the Plutonium Project would have been immeasurably poorer without it. Yet, it is now clear that informed consent was

FIGURE 7.13. Excretion of plutonium over an approximately five-year period using the data from the patients described in the text and rates determined from Los Alamos workers to extend the time beyond that shown in figure 7.12. The derived expressions use the same symbols as in figure 7.12. (Redrawn from Langham et al. 1950.)

honored more in the breach than in the performance. (There was only one case of documented informed consent.) When it became obvious that public scrutiny could no longer be prevented by keeping a security classification around the work, there was something of an uproar in the Washington offices that had inherited the problem from MED and in turn AEC, i.e., ERDA; and covert apprehension in the university hospitals involved. After great travail, it was decided that those patients who were still alive should be informed of what they received.

Like many crises agonized over in the anticipation, the response was remarkably mild. (One patient was not informed because her doctor judged that the knowledge would be detrimental to her health.) Perhaps this was because the patients were so elderly that they felt they had already weathered hazards of much greater magnitude. But obviously in view of the reputation that plutonium has now, such an experiment would be unthinkable, with or without informed consent. Thus, we will have to be content with what could be gathered during the war years, plus extensions through workers in the postwar years, and eventually results from the U.S. Transuranium Registry (chapter 16).

Reiteration and reinterpretations of this work were obviously necessary as correlative information accrued during the postwar decades. These will be examined in succeeding chapters, especially the work of Durbin. But, for completeness, let us give the status of the patients as of 1976, close to the end of the years of factual review for this book.

Case	Status	Age at Death	Survival Time ^(a)
Cal-1	Deceased	79	20 yr 8 mo
Cal-2	Deceased	5	8 mo
Cal-3	Still living		
Chi-1	Deceased	68	5 mo
Chi-2	Deceased	55	17 day
Chi-3	Lost to follow-up		
HP-1	Deceased	82	14 yr
HP-2	Deceased	51	2.5 yr
HP-3	Still living		
HP-4	Deceased	20	2 yr
HP-5	Deceased	57	5 mo
HP-6	Still living		
HP-7	Deceased	60	8 mo
HP-8	Still living		
HP-9	Deceased	66	1 yr
HP-10	Lost to follow-up		
HP-11	Deceased	68	6 day
HP-12	Deceased	60	7 yr

(a) This is the time after injection, but death was always from causes unrelated to the presence of plutonium.

IV. Toxicology of Plutonium

Work on the biological effects of plutonium in animals was concentrated during the years of World War II at Chicago and Rochester. Berkeley remained more concerned with metabolism.

A. Acute Effects

The first description of the acute biological effects of plutonium, in contrast to inferences of effects from its metabolic behavior, is found in the report on the effects of "product" on a dog (Cole and Prosser 1945). This was a broad-gauge study in which most of the usual physiopathology used in clinical medicine was applied. The dose was large (0.36 mg/kg), and the animal's clinical condition went downhill so fast that it was sacrificed after sixteen days and four hours. Blood samples taken in the interim demonstrated a gradual drop in plasma protein, rather striking shifts in electrophoretic patterns (increase in α_2 globulin), and changes in blood chemistry similar to acute x-ray exposures (300 to 600 roentgen units) with some differences. The dog exposed to plutonium showed less hemorrhage than did dogs exposed to x rays, and ulcers of the duodenum and jejunum did not appear as they did after x-irradiation. The hematological changes were not remarkable in this short period except for a drop in the number of leucocytes in peripheral blood and some fall in erythrocyte count. Yet, the animal was obviously acutely ill; and insofar as one experiment has meaning, it demonstrated greater sensitivity to plutonium in the dog than in mice.

1. Effects in Rodents

Although there were other "notes" in Met Lab monthly reports, the next full report on effects appeared in the large report on *Toxicity and Metabolism of Plutonium in Laboratory Animals* written in August 1947 (R. D. Finkle et al. 1947). In chapter IV of the report, Snyder, Kisielewski, and Finkle describe the survival and growth of plutonium-injected animals; in chapter V, the effects of ingested plutonium (Snyder, Lawrence, and Finkle), and in chapter VI, the hematological effects (Jacobson and Simmons). Since this rather complete document did not get published, some details will be given here. The animals were mice (ABC and CF1), rats, and rabbits.

a. Lethal Action

The LD₅₀ in 30 days after intravenous injection in rats was about 0.09 $\mu\text{Ci/g}$, in 60 days 0.06 $\mu\text{Ci/g}$, at 90 days 0.06 $\mu\text{Ci/g}$, and at 220 days about 0.03 $\mu\text{Ci/g}$. The corresponding values for mice were 0.08 $\mu\text{Ci/g}$, 0.07 $\mu\text{Ci/g}$, and 0.05 $\mu\text{Ci/g}$ for 30-, 90-, and 210-day LD₅₀ values. These figures can be compared with those for fission products such as ⁸⁹Sr-⁹⁰Sr discussed in chapter 6. The LD₅₀ values for these are on the order of 5 to 8 $\mu\text{Ci/g}$. Thus, plutonium appears to be more toxic acutely by a factor of about one hundred. Allowing a factor of ten for the then-accepted relative biological effectiveness (RBE) of alpha particles, another factor of ten is left that requires some other explanation. If the currently advocated RBE of twenty for alpha particles is used, only a factor of five requires other explanation.

The data are presented in extenso in the original document.

b. Effects on Growth

Retardation of growth was detected at levels as low as 0.0078 $\mu\text{Ci/g}$ in rats and 0.0013 $\mu\text{Ci/g}$ in rabbits. This retardation began only after several weeks of apparently normal weight gain and a long plateau.

c. Clinical Findings

The rats showed extensive gastrointestinal hemorrhage, hyperemia of lymph nodes and gonads, and extensive liver damage. Skeletal lesions (fractures) were slower to develop and appeared at doses of 0.031 and 0.016 $\mu\text{Ci/g}$ in rats. One osteogenic tumor was seen and three soft tissue tumors, all after 150 days.

Symptoms in the mouse were comparable and in the same dosage region.

d. Mechanisms

The authors speculate that some of the toxicity seen may be due to *chemical toxicity* of plutonium as a heavy metal. This was stimulated in part by a shock-like syndrome occurring in the mice receiving intravenous doses as high as 200 mg. (A similar experience was encountered in rats receiving large intravenous doses of radium in the work at Rochester as mentioned in chapter 1.)

The idea of a specific chemical effect was strengthened further by the fact that the acute effects of plutonium proved to be about the same as those of similar quantities of ²²⁶Ra. Since at that time the simple calculation of relative energy and half-life of ²³⁹Pu versus ²²⁶Ra predicted that plutonium should be about one-fiftieth as radiotoxic as radium, the extra toxicity was concluded to be attributable to a chemical action. Other more probable explanations emerged later, but the idea of a component of chemical toxicity for plutonium reappears like a Phoenix throughout the literature, even to the present. Pathology was entirely consistent with radiation effects, however.

e. Effects of Ingested Plutonium

The number of animals was very small, and the almost negligible absorption from the gastrointestinal tract made this more a metabolism than an effects experiment. A dose of about 17 $\mu\text{Ci/g}$ was not lethal to the mouse but caused marked growth retardation as well as lethargy, labored breathing, etc., which cleared up by the forty-eighth hour.

f. Hematological Changes

At these acute levels, changes in hematological constituents of peripheral blood of the rodents were a very sensitive indicator of damage. The data in this report are, however, not complete, since many of the animals were still living at the time the report was written. On the whole, the experiment shows effects identical to those occurring with other radioactive materials, and there are not marked species differences. Also, the differences between external radiation with x rays, fast neutrons, and gamma rays and those of plutonium are qualitatively small. Unfortunately, it is not feasible to gauge from these data to what extent quantitative differences exist. The doses given were well below the LD_{50} levels for plutonium, and there seemed to be a threshold between 0.003 and 0.0003 $\mu\text{Ci/g}$ in mouse, rat, and rabbit. The numbers of animals were acceptably large, and the observation period was approximately three hundred days.

2. Effects in the Dog

An extensive clinical study of acute and subacute effects in the dog is presented by Painter et al. in an AEC declassified report (Painter et al. 1946). The report is about equally divided between careful and extensive studies of the metabolic behavior of plutonium and broad-ranging clinical physiology and physiopathology. Since this is another paper that was not published as planned in the NNES series, it will be examined in some detail. Fortunately, some of the findings are included in a paper by Prosser and collaborators in the Plutonium Project issue of *Radiology* in 1947. This provides many comparisons between external radiation and radioisotopes and among radioisotopes (Prosser et al. 1947; Prosser and Swift 1949).

The plutonium was used in its soluble +6 citrate form in all but one dog and was given by intravenous or intramuscular injection. Five dogs received high doses, eleven dogs "chronic low doses" but not low enough to be regarded as "chronic" today. There were four dogs and one puppy in the intramuscular series that received relatively lower doses.

a. Acute Toxicity

Although the series is small, the acute LD_{50} (death in about 15 days) was calculated. It was about 0.3 $\mu\text{g/g}$ (0.02 $\mu\text{Ci/g}$) net retained dose for intravenous administration and between 0.35 and 0.68 $\mu\text{g/g}$ (0.02 to 0.04 $\mu\text{Ci/g}$) for intramuscular injection. The authors consider this of the same order of magnitude as in the rat. Since the figures with the rat were more than double and were for 30 days it seems more correct to conclude that the dog shows greater sensitivity to plutonium acutely, despite the small size of the group studied. The "subacute" dose, with which the animals (adult mongrels) lived from 90 to 234 days, was less than a factor of two below the levels mentioned above. Either the dog is exquisitely sensitive to small differences in the size of a plutonium dose, or this pioneering series was too small to permit a valid quantitative measurement of toxicity.

b. Clinical Findings

This portion of the report gives a meticulous description of the clinical course of each dog with some exceptions.

Gross changes in appearance and activity of most of the treated dogs did not appear until a week or so before death. The general picture was comparable to x-irradiation, except there were fewer hemorrhages in the plutonium-treated animals. Fever and evidence of acute illness began about the tenth day but not in all cases; changes in heart rate were comparable to x-irradiated animals, but in this, like most other signs, the plutonium dogs seemed to be more variable. Hematological changes are presented in detail and are consistent with radiation effects. Body weight loss began almost immediately in the acute-level animals. At autopsy, the dog injected with plutonium that died acutely resembled "dogs which died two weeks after single doses of x-radiation except that hemorrhages and ulcers were less abundant." The x-ray dose producing comparable changes in a comparable time was 50 r per day.

The picture was quite different between the two subacute dogs. One died at 90 days and resembled dogs who had received "several months of treatment with 12.5 r daily x-radiation" in that anemia was an important factor. The other dog, which lived 234 days, showed marked liver damage much like that seen in rodents. There was no leukopenia or anemia. Since the dogs were mongrels, this difference may represent lack of comparable genetic make-up, but no proof can be offered. The case does speak well for the movement that began about this time to employ only genetically homogeneous animals in such important and expensive work.

3. Summary of Clinical Findings in All Animals

In the plutonium conference held in May, 1945 (Nickson 1945), Brues summarized clinical effects of plutonium. A few items are in addition to those in the CH-3783 report and a few differ. At acute levels:

1. CF1 mice show only slight anemia, while ABC mice show profound anemia at the same dose.
2. Gross renal damage occasionally follows lethal doses of plutonium.
3. The acute lethal dose is quoted as 0.4 mg/kg in the dog and 1 mg/kg in rodents given intravenous doses, while it is 4.5 mg/kg in mice after intramuscular injection. These are roughly comparable to the figures discussed earlier.
4. Subacute plutonism is described in which the animal survives for many months although declining gradually (e.g., 0.3 mg/kg of +6 citrate).
5. Some hematological effects occur in some groups of animals at all doses down to 0.05 mg/kg, while in others the first significant changes occur at 0.1 to 0.25 mg/kg.
6. Amounts as small as 1 μ g deposited locally may produce ulceration and suspicion of carcinogenic changes.

Throughout this summary, the great variability of response between one group of animals and another is emphasized. No explanations were forthcoming at the time.

At this same conference, the first formal comparison was made of the toxicities of radium and plutonium and of polonium and plutonium. This was reported by R. M. Fink and is the first introduction of work at the University of Rochester. This will be reviewed in the section on chronic toxicity.

4. Summary of Histopathology

The microscopic pathology after acute doses of plutonium was not dwelled upon voluminously during the work of the war years. This was due in part to the similarity to x-irradiation and partly to the much greater interest in examining the longer-term effects. Yet, there was the usual thorough study done by Bloom. In his remarkable treatise on the histopathology of radiation (Bloom 1948), of about one hundred mice used a large number were examined within a few days of injection, while the longest period given is seven months; ditto for the thirty-four rats receiving plutonium. The results are given organ by organ, system by system, and in relation to external radiation and other radioisotopes. No isolated summary can be given except to remark that the plutonium effects tended to be "focalized." In a summary paper in *Radiology* (1947), Bloom stresses the marked difference experienced between rats and mice vis-à-vis bone-seeking elements. In mice, "since we see the mice when they have practically ceased growing, the experiments with the radioactive isotopes in these animals would correspond fairly well to the deposition of these substances in adult human beings. In the case of rats, the effect of bone-seeking isotopes is a bit different, since the rat is, for all practical purposes a continuously growing animal. In the rat the isotopes that seek bone come down not only in old bone but predominantly in the zone of new bone growth in the metaphysis, and for all practical purposes they kill this entire zone" (Bloom 1947, pp 346-347). Examples are given.

In the 1945 plutonium conference cited earlier (Nickson 1945), the Chicago group introduced estimates concerning the relative histopathology of x ray, ^{89}Sr , plutonium, and radium. By the use of a numbering system for degree of damage, a procedure that most pathologists seem to shun like a plague, they presented some interesting correlations. They are reproduced here as table 7.2. It is unusual, and may be regarded as an example of the simpler days when broad correlations of new information were more important than minutiae of specific problems.

5. Effects on Tissue Metabolism

An almost unique contribution to studies on the effects of radioisotopes is the work of Barron et al. (1946) on the tissue metabolism of rats treated with plutonium. In the chapter on uranium (chapter 2), we reviewed work showing the effect of uranium on the metabolism of isolated cells. The plutonium work was entirely different in that the studies were made on tissues removed from animals after the development of acute plutonism.

They found both respiration without substrate, and oxidation of pyruvate and anaerobic glycolysis were greatly depressed in spleen tissue from the affected animals. Liver showed similar decreases in metabolic rates, and these seemed to be correlated with the degree of macroscopic atrophy seen. Phospholipid synthesis was not affected.

Using ^{32}P as a tracer, they found that its transport across the intestinal wall was not affected.

Metabolism of the adrenals was profoundly affected, while kidney showed some but lesser changes. Heart, submaxillary gland and lungs (after intratracheal instillation) were essentially normal. After ingestion of plutonium, there was inhibition of oxidative processes in small intestine, but anaerobic glycolysis remained normal.

TABLE 7.2. Comparison of Histological Effects of X-Ray (single dose), Radium, Plutonium, and Radiostrontium*

Agent	Dose	Range of Intervals	Bone Marrow-rbc	Bone Marrow Gran.	Bone Marrow Growth Damage	Cut Epithelium	Gut Lymphatic	Mes. Lymph Node	Skin	Spleen Lymphatic Damage	Spleen Myelopoiesis Damage	Spleen Myelopoiesis Stim	Testis	Ovary	Thymus	Liver	Other Organs
X-ray	350 r	1hr-21d	10a	8n	0	4n	3n	3n	0	2n	8n	6n	0	2e	4n	0	0

* The numbers 1-10 refer to degree of damage from 10% to virtually 100% destruction. All are very rough estimates. The letters "a-e" refer to the extent of recovery from the height of damage, 80% to 10%. The letter "n" indicates complete recovery. Under "Spleen Myelopoiesis - stimulation" the figures are relative only and do not indicate multiples of the normal. The letters under this heading indicate return to normal as in the regeneration from damage. Other signs have the following meaning:

+ damage incapable of quantitation
 ? insufficient data
 0 no change
 ± questionable change
 — not examined

Source: Reset from Nickson 1945.

Studies such as this are very difficult to interpret. With considerable atrophy of some tissues or organs, the weight of live tissue contributing to the metabolic processes is difficult to gauge. Without a measure of this quantity, changes in metabolic rate per gram of sample may be quite misleading. Also, it is difficult to separate out effects of plutonium per se and secondary effects due to the general illness produced by the plutonium. While popular for a while in toxicology, work of this type did not continue much longer because effects on specific enzymatic processes could contribute more information.

Thus, while this study is unique, it is of interest primarily to show what was thought and what was tried rather than for its contribution to the understanding of plutonium toxicology.

6. Recap of Acute Toxicity: Comparison to Radium

In the later years of World War II, the results of two major animal experiments began to yield useful information. These were the studies at the University of

Rochester Project (chapters by Boyd et al. [1950a,b] in Fink 1950) reported in some detail in chapter 1 and the early results of a series of experiments at Chicago. Although the reports are post-World War II, the work was done either entirely (Rochester) or in the acute phases (Chicago) during the war years and should be considered in this chapter devoted to that period.

As soon as it was known that plutonium was a bone seeker and was retained avidly in the body, analogies to radium were drawn, as we have already seen. The quantitative aspects as they bore on standard-setting will be looked at in detail in chapter 16. Suffice it to say here that the early investigators were clairvoyant enough to let the differences in microdistribution in bone of these two elements raise a red flag to basing conclusions on simple calculations of relative energies and half-lives.

The first information on acute toxicity seemed to confirm the wisdom of this cautious approach. But conclusions had to wait for some quantitatively reliable data with plutonium and radium compared in the same experiment. We will consider the acute toxicity in this section.

The toxicity of ^{239}Pu relative to ^{226}Ra in the Rochester rats is given in table 7.3, modified from Boyd et al. 1950a, p. 251. Obviously, ^{239}Pu is markedly more effective than ^{226}Ra as an acute toxic agent on a microcurie basis.^(a) Part of the phenomenon lies in the surprisingly low toxicity of ^{226}Ra acutely.

TABLE 7.3. Toxicity of ^{239}Pu Relative to ^{226}Ra

Days Following Injection	Approx. LD ₅₀ ($\mu\text{Ci/kg}$)		Pu/Ra Toxicity Ratio
	Ra	Pu	
10	8000	200	40
20	4000	130	30
30	3000	100	30
60	1300	60	20

Source: Modified from Boyd et al. 1950a.

An analysis by Brues (1951) contains not only the Rochester and Chicago data but a 1914 experiment (Proescher and Almquest 1914). The results are shown in table 7.4, modified from Brues (1951).^(b)

The toxicity of plutonium relative to radium is about thirty at thirty days in both studies. But note that the ratio seems to be decreasing with the time span in table 7.3. This is important, as we will see soon.

All of this work refers to acute lethality, not the development of any specific pathologic entity. It solidifies the view expressed earlier that plutonium is considerably more toxic than radium, rather than a factor of fifty less, as the relative half-life and energy deposition would predict (see chapter 16). We have already noted that plutonium is more toxic acutely than the fission products by a factor of one hundred. Those who had urged extreme caution in handling plutonium were very glad they had insisted on their position, despite the extra costs in

(a) On a weight basis they are nearly equal.

(b) Note that the units are microcuries per kilogram in table 7.3 and microcuries per gram in table 7.4.

construction and operations within the MED (cf. Seaborg quotation earlier in this chapter).

Does this information prove that plutonium is “the most toxic element known to man”? Hardly, as we will see in a later section.

B. Long-Term Toxicity of Plutonium

1. Survival and Lethality

Major efforts were expended in the postwar years to address all aspects of the long-term toxicity of plutonium. For the moment, we will examine only the information gained during the war years and analyzed immediately thereafter.

The Rochester experiment was done and reported in two phases, as described in chapter 4. The “pilot studies” employed fewer animals per point, but the dosage range was greater than in the larger “simultaneous studies” (see also description in chapter 1). Figure 7.14 shows the survival time of the Rochester rats up to three hundred days as a function of injected dose of ²³⁹Pu, ²²⁶Ra, and ²¹⁰Po in microcuries per kilogram in the pilot experiment. Note that the relative toxicity of radium seems to be increasing rapidly with longer survival times and might even approach a ratio of 1:1 versus plutonium if sufficient time were involved. The same picture appears if the ordinate is expressed as calculated radiation dose. In figure 7.15, the same data are plotted on a weight basis. Here we see the near equivalence of radium and plutonium and the far greater effectiveness of ²¹⁰Po in producing lethality because of its high specific activity.

FIGURE 7.14. Mean survival time of Wistar-Rochester rats as a function of intravenously injected dose of ^{226}Ra , ^{239}Pu , or ^{210}Po . The radium experiments differed in their polonium content. Experiment 1 had 0.1 ^{210}Po , experiment 2 had 0.2, and experiment 3 had 0.07. This difference was due, of course, to waiting different times after the last purification of the radium preparation. Experiments 1 and 3, having the least polonium, are probably the best representation of ^{226}Ra . (Redrawn from Boyd et al. 1950a.)

FIGURE 7.15. The same experiments as plotted in figure 7.14 but on a weight basis. Note that plutonium and radium are almost identical on this basis. (Redrawn from Boyd et al. 1950a.)

In figure 7.16, the data from the simultaneous experiment are shown. Here there were many more animals per point, but unfortunately the choice of doses for radium did not extend much beyond 110 days survival time, and the whole experiment covers survival times only up to 160 days.

FIGURE 7.16. Comparative toxicity of ^{226}Ra , ^{239}Pu , and ^{210}Po in the much larger simultaneous intravenous experiment in the Rochester-Wistar rat. (Redrawn from Boyd et al. 1950b.)

Obviously, the same general trend appears toward a lower ratio of plutonium to radium with longer survival times. But no ratio for truly chronic periods can be decided upon. It can be concluded that the ratio of thirty seen for LD_{50} in thirty days is probably too high for application to longer periods. Indeed, the Rochester group calculated toxicity relative to radium, including some extrapolation from plotted curves as shown in table 7.5. Obviously, it cannot be said that the toxicity ratio becomes unity at longer times.

TABLE 7.5. Calculation of Plutonium/Radium Toxicity Ratio From the Rochester Experiments

Days After Injection	Approx. LD ₅₀ (μCi/kg)		Approx. Toxicity Ratio
— Pilot Experiment —			
	Ra	Pu	
100	600	40	15
200	150	23	6.5*
300	30	15	2.0**
— Final Data Compilation± —			
60	—	—	16
80	—	—	12
100	—	—	9

* This ratio was not calculated by the authors because of the small number of animals. It is done here for convenience more than significance.

** By extrapolation of the plutonium curve in figure 7.14.

\pm From the authors' final summary using their views on the validity of each set of data contributing.

Source: Modified slightly from Boyd et al., chapters 7 and 8 in Fink 1950.

To give the reader a better feel for the real data, since the previous figures show either no points or median values, figure 7.17 is reproduced from the Fink volume (p. 332). It shows the survival times of rats against the microcuries of plutonium injected per kilogram of body weight.

FIGURE 7.17. Survival curve of Rochester-Wistar rats versus microcuries of plutonium injected per kilogram body weight showing individual points and median points. (Redrawn from Boyd et al. 1950b.)

The issue of what the relative toxicity is at very low doses of plutonium or radium was addressed by Brues (1951) in the paper already discussed. He plotted curves for 5%, 10%, and 50% survival and obtained ratios of plutonium/radium of 12.8, 9.8, and 14.1, respectively. Here the ratio appears nearly invariant with dose rather than converging at lower doses. By calculating a survival function:

$$\alpha = \frac{1}{t} - \frac{1}{t_0}$$

where t is the survival time of the treated groups and t_0 that of the control group; and assuming each reciprocal of survival times represents a "rate of aging," they calculate also a survival function, β . This is defined as α/dosage and has been observed to be invariant over a wide range of doses of x-irradiation. Putting all of their findings with rodents, the Rochester data, and some figures for dogs and rabbits into the system, they calculate values of the function for each experiment. They ranged from 0.8 to 3.5×10^{-5} for radium and from 7 to 31×10^{-5} for plutonium. This would argue that the toxicity ratio is relatively invariant, or at least that it shows no regular trend with dose.

The Chicago workers conclude that the problems of too little information at low doses and long survival times in the Rochester data and problems of infectious pneumonitis in the animal colony at Chicago leave the final decision for further experiments. But they propose that the most probable ratio of toxicity of plutonium to radium in the intermediate dosage range is ten for long-term effects. This would be an underestimate for shorter-term effects.

This is how the situation stood at the end of the war work. All of it was based on survival times, not specific pathology. Brues went to the Tri-Partite Conference on Internal Dosimetry in 1949 (see chapter 16) with a figure of fifteen in his mind for long-term relative toxicity ratio. In chapter 8, we will see that the enormous surge of postwar work on plutonium toxicology supports the view that ^{239}Pu is at least ten times as effective as ^{226}Ra in producing many specific long-term pathological changes such as bone cancer.

2. Long-Term Pathologic Changes

The two large experiments at Rochester were not at low enough doses to see truly long-term pathologic changes. There is careful documentation in the chapters on both the "Pilot Studies" and "Simultaneous Studies" for the findings in animals dying up to 260 days after injection. Marked changes, comparable to doses of about 550 R of whole-body x-radiation, were produced in the hematopoietic system, bone, and testes. There were occasionally changes in lung, liver, stomach, kidney, heart, adrenal, and subcutaneous tissue. The primary effect was loss of functional cells and atrophy in the hematopoietic system and testes, mostly degenerative changes in bone and cartilage with disorganization of the areas of bone growth, and hemorrhages in numerous organs. These were not universal in occurrence except for the changes in bone. Liver showed mild to marked changes depending on dose.

The Rochester animals did not survive long enough, at least not in sufficient numbers, to show the development of bone cancer, and the pathology reports are essentially silent on the presence or absence of precancerous changes.

The first substantive discussion of carcinogenic changes came from Brues, Lisco, and M. Finkel (1946). Their findings with fission products have already been described (chapter 6). Bone tumors appeared in the rodents less frequently following administration of plutonium than after ^{89}Sr . They attribute this to the fact that many of the plutonium animals died from other causes (e.g., liver damage) before bone cancers could develop. They also postulate that the latent period for bone tumor development is considerably longer with plutonium than with strontium, although they give no information about the basis for this postulate. However, they did find what appeared to be osteogenic sarcomas. The date of preparation of this report is unknown; the year of declassification is 1946. Thus, the fact that plutonium could produce bone tumors as does radium must have been known within the MED biomedical community by at least 1945. The lowest dose inducing an osteogenic sarcoma within five hundred days in rodents was 0.02 mg/kg (1.25 $\mu\text{Ci/kg}$).

In a published summary of this work in the Radiology Symposium (Lisco, Finkel, and Brues 1947), it is stated that bone tumors were seen "frequently" in mice, rats, and rabbits at plutonium injection levels ranging from 0.05 to 4.5 $\mu\text{g/g}$, with a minimal latent period of two hundred days. The majority of the tumors occurred in the spine, in contrast to the sites of incidence with strontium (62% versus 22%). This difference was considered as possibly due to the greater affinity of plutonium for collagenous tissue than for bone mineral.

No liver tumors were reported in either the earlier or later work except for small adenomata. The authors remark on the severity of the effects in liver, which is ordinarily considered fairly radioresistant.

3. Is Plutonium the Most Toxic Element Known to Man?

This statement was made during the war years, perhaps in part to ensure support for the needed protection measures, in part to secure full cooperation of

the workers, and in part because the accumulating data were pointing in that direction. Like all such sweeping generalizations, it is a considerable exaggeration.

As we have seen in this chapter, plutonium (i.e., the isotopes of most concern for their biomedical effects, ^{238}Pu and ^{239}Pu) are far ahead of the fission products in acute toxicity. But in comparison to the "supertoxics" in the world of chemical toxicology, plutonium is far behind. This was discussed by Stannard (1976) in a summary paper, some data from which are excerpted in table 7.6, along with some of the data from this chapter.

TABLE 7.6: Acute Toxicity of Plutonium Compared to "Supertoxics"

Substance	LD ₅₀	Route	Test Organism
Botulinus toxin A	$5 \times 10^{-6} \mu\text{g/kg}$	IPR	Mouse
Crystalline botulinus toxin	$7 \times 10^{-9} \mu\text{g/kg}$	IPR	Mouse
Diphtheria toxin	$1 \times 10^{-4} \mu\text{g/kg}$	IPR	Mouse
Bufotoxin	$390 \mu\text{g/kg}$	IV	Cat
Curare	$500 \mu\text{g/kg}$	IPR	Mouse
Strychnine	$500 \mu\text{g/kg}$	IPR	Mouse
Potassium cyanide	0.3 mg/l	INH	Human*
Hydrogen cyanide	1.0 mg/kg	INH	Human*
Methyl mercury	7 mg/kg	Ingestion	Guinea pig
Arsenic trioxide	1000 mg/kg	Ingestion	Human
Plutonium	0.3 mg/kg	IV	Dog
	1.4 mg/kg	IV	Rat ^(a)
	1.3 mg/kg	IV	Mouse ^(a)

* Estimated from accident experiences and extrapolation from animal tests.

There are indeed many substances extant that are far more dangerous in terms of acute exposure than is plutonium. There are even some radioisotopes of greater concern acutely, e.g., ^{210}Po and some of the transplutonic. However, they are not as available in quantity as plutonium might be.

What of long-term chronic toxicity? We have seen in this chapter that plutonium is well toward the head of the list in terms of effects on survival on an activity basis. But on a weight basis, it and radium are essentially equal. The wartime work stopped short of finding how effective plutonium really is as a carcinogen; this will unfold in chapter 8.

Meanwhile, perhaps we should, in anticipation, modify the statement to: "Plutonium is probably quite an effective carcinogenic agent in the bone of experimental animals." More will appear in chapter 8, including the fact that strontium can actually produce more tumors at its most effective dose levels.

V. Wartime Biomedical Work with the Transplutonic and Related Actinide Elements

A. General Considerations

By transplutonic elements we mean, of course, those with atomic numbers above plutonium. For our present purposes, these are primarily americium (element 95) and curium (element 96), but we will consider also neptunium and protactinium, which are below plutonium. The still heavier elements, although brought into being in part before the end of the war, did not receive biomedical research attention until later and will be omitted for the present.

Compared to plutonium and the fission products, these elements do not occur in large enough quantities to present the "new dimensions" described for plutonium. Yet, they have properties that make it important that they be reckoned with.

B. Metabolism

Figures 7.4 and 7.5 give the broad perspective on metabolism of these elements in bone and liver, which are the principal sites of deposition. All of them deposit in bone and remain for long periods, but the uptake is significantly less than for plutonium. Curium and americium, in which we are most interested, deposit to less than half the extent of plutonium. Neptunium deposits to almost the same extent as plutonium. On the other hand, americium and curium deposit to a much greater extent in liver than does plutonium. Very little neptunium deposits in liver. But those that deposit in high concentration also leave the liver very rapidly so that by sixty-four days all but neptunium are about equal in amount in liver.

Americium-241 was studied in some detail by the Berkeley group and reported on in the open literature by Scott et al. (1948b). This report expands on the facts noted above from the Hamilton review. The high content of liver initially and lower but more permanent fixation in bone are shown in table 7.7, modified from Scott et al. (1948b).

Obviously, the total amount in liver initially is impressive, but it is bone that holds essentially constant in content, while liver rapidly loses its americium. Incidentally, as the liver loses, the feces gain, which supports the notion that the americium is excreted in the bile.

These were complete balance experiments and included collection of excreta. Like plutonium in the rat, feces contained by far the larger fraction of total excretion, except in the first day. But it kept rising with time even to the end of the experiment.

Autoradiographs showed microdistribution in bone much like the rare earths and plutonium, i.e., deposition largely on the trabecular surfaces. In addition, americium seemed to accumulate around the small blood vessels of cortical bone. Cerium and element 61 (now promethium) were the only other radioelements

found to exhibit this particular deposition up to the time of this paper. Curium was added in the next year.

Of the other soft tissues, only kidney showed accumulation of significant amounts in the one- to sixteen-day interval.

Curium-242 was studied soon after americium also by the Berkeley group (Scott, Axelrod, and Hamilton 1949). At that time, it was the heaviest known element. The experiments and the results were closely similar to the work with ^{241}Am . The bone and liver contents are so much like those shown in table 7.7 that a separate presentation seems unnecessary. There was the same rapid loss from liver and build-up in feces, but the loss after 120 days was somewhat slower than for americium.

TABLE 7.7. Distribution of Americium-241 in Selected Tissues of the Rat after Intramuscular Injection

Time, days	Liver		Bone	
	%/Organ	%/g	%/Organ	%/g
1	54.8	6.07	23.2	1.01
4	35.7	4.24	19.1	0.66
16	15.3	1.64	25.6	1.25
64	1.94	0.18	25.0	0.96
256	0.68	0.081	24.8	0.94

Note: The data have been corrected for the fraction unabsorbed at site of injection and deviation of recovery values from 100%.

Source: Modified slightly from table II, Scott et al. 1948b. Reprinted with permission of American Society of Biological Chemists, Inc., Bethesda, Maryland; copyright 1948.

The microdistribution in bone seen by autoradiography was similar to that for americium, plutonium, et al. This included deposition around blood vessels in cortical bone.

The almost identical behavior of these two transplutonic actinides is consistent with the theory of the actinide series (see Scott, Axelrod, and Hamilton [1949] and Seaborg [1963] and other papers listed in the bibliography). Actually, much the same pattern is seen in the lanthanide rare earths since the chemical properties depend on the outer valence electrons, and these remain essentially the same. The additional electron for the successive elements goes into the 4f-electron shell, which is not complete. Among other things, the actinide series theory predicts very stable +3 valence states for members like americium and curium. This was found to be true and helped in their separation. Thus, on general principles we would predict that these would be poorly absorbed from the gut, as is plutonium. This is shown to be true for both elements in the papers cited.

It is tempting to argue for these elements, as was done for plutonium, that the high liver content reflects entrapment of colloidal aggregates by the RES. This is negated in both cases by the fact that spleen takes up only about one-fiftieth of the concentration in liver, even at early times.

Neptunium-237 has such a long half-life (2.2 million years) that it requires 1.5 mg to produce an activity of 1 μ Ci. Therefore, it seemed likely that chemical toxicity problems would predominate with it if there is to be any toxicological problem at all. This and other neptunium isotopes were studied to only a limited extent during the war. Very recent postwar work has cast it in a somewhat different light.

C. Reasons for Interest in the Transplutonium Elements

The inherent interest in checking biological and biochemical behavior of not only the transplutonium elements but all members of the lanthanide and actinide series is sufficient to stimulate biomedical investigations, especially on the "metabolism" of the various members as a function of their relative position in their respective series. But there are also some quite practical reasons for interest:

1. The transplutonics are formed by successive neutron capture reactions in nuclear reactors and in fission weapons. In the former, they may accumulate in sufficient quantity to require personnel protection and understanding of their behavior vis-à-vis plutonium.
2. Most of them are alpha emitters or decay by spontaneous fission, and all are radioactive. Their half-lives are shorter than that of ^{239}Pu , and they have high specific activities. The mass required to be biologically significant may be hardly measureable. Thus, they must be followed through their radioactive properties.
3. The relative biological effectiveness of elements that decay by spontaneous fission is quite high.
4. Americium-241 is a daughter product of ^{241}Pu , which may occur alongside ^{239}Pu in considerable quantities. It has utility for bioassay because of its 59.5-KeV gamma ray. But we must also reckon with it as a product of reactor operations and in weapons debris.
5. Toward the end of the war, the properties of some of the transplutonics for special uses as heat sources and in medical applications led to much interest in producing them in much larger quantities than even the normal accumulation in the production processes then extant. This stimulated even more interest in their biomedical behavior. The story will unfold in subsequent chapters.

VI. Summary and Commentary

The second major new dimension that faced the biomedical community with the decision to explore nuclear fission energy was a qualitative as well as a quantitative one. The synthesis of plutonium and the development of the radioelements of the actinide group posed virgin territory to explore. There was no previous experience to draw upon for predicting their metabolic behavior. Furthermore, the plans called for the production of kilograms, even tons, of some of these new elements that had to be produced in huge reactors and purified in enormous chemical separations plants.

The chemistry of the actinide elements is so intimately bound up with the biomedical studies that the chapter contains a summary of it. This includes the realization that the old periodic table of the elements was not correct in the

region of the new heavy elements and depiction of the modified periodic table as it was rewritten by the Seaborg group.

The early biomedical work on these new elements began at Berkeley, as it did with the fission products. Its genesis is outlined in the chapter. The basic behavior seemed much like radium, but, as with the fission products, autoradiography demonstrated some real differences in microdistributions. As the newer actinides were synthesized, the similarities and differences became even more apparent.

In addition to metabolic work, there were major studies on effects of plutonium at the Metallurgical Laboratory in Chicago and at the University of Rochester Project. There was also much activity in terms of monitoring of employees and determination of the kinetics of excretion at Los Alamos. The Chicago and Rochester work included both larger groups of animals and larger animals than did the Berkeley tracer studies. Though plutonium was obviously a bone seeker, there were sufficiently different microdistributions to raise warnings regarding any simplistic calculations of maximum allowable concentrations or body burdens. As the effects work progressed at both Chicago and Rochester, it became apparent that plutonium was considerably more effective than radium as a carcinogenic agent. This was puzzling since both were alpha emitters, and plutonium had both a lower energy and a longer half-life than radium. The explanation concerned the Chicago and Berkeley workers during most of the later war years and generated large experiments for further checking. These were done mostly in the postwar years. The cause turned out to be the difference in microdistribution.

There has been no large population of humans exposed to plutonium as there was to radium. There were occupational exposures, not only to plutonium, but to the other actinides, especially at Los Alamos. A number of hospital patients at California, Chicago, Oak Ridge, and Rochester received tracer quantities of plutonium and were studied as long as possible. Basic metabolic behavior appeared to be similar to that seen in the animal experiments and supported the then-extant exposure limits.

Right at the end of the war, in 1947, the data for plutonium and the other actinides were used at a series of three-nation conferences on radiation exposure limits (The Tri-Partite Conferences). They required careful interpretation, for the most conservative interpretation could have closed Los Alamos. Details are reserved for chapter 16 on standards.

During the war years, a good start was made on the inhalation toxicology of plutonium. This involved primarily Richard Abrams at Chicago. Details are reserved for chapter 9.

Whereas the wartime investigations of the fission products went far toward answering the major questions, the work with the actinides seemed to keep opening almost as many questions as it settled. Therefore, there was a large carry-over into the postwar years, as described in chapter 8.

OUTLINE

POST-WORLD-WAR-II RESEARCH ON THE ACTINIDES AND FISSION PRODUCTS

Capsule Chronology	381
Overview	385
I. Part of a Golden Era	386
II. Extensions and Consummations	386
A. Argonne National Laboratory	387
1. Relative Toxicity in the Mouse	387
2. Radiostrontium in Mice	393
3. Other Work at Argonne	396
a. Lethality and Carcinogenicity of Radiostrontium in Other Species	396
b. Metabolism of Strontium	397
c. Locally Deposited Isotopes	398
d. Plutonium at Argonne National Laboratory in the Postwar Years	398
4. Comment	399
B. University of California at Berkeley	399
1. Extensions of Research on Fission Products and Heavy Metals	399
a. Laboratory Report on Localization of Cerium-144	400
b. Study of the Distribution of Radioisotopes of Some Heavy Metals	400
c. Work on Metabolism of Strontium-90 in Monkeys	400
2. Systematic Study of the Lanthanides	402
3. Iodine and Related Elements	406
4. Actinide Research in the Postwar Years	406
5. Radium-223, the Daughter of Actinium	408
6. Crocker, Donner, and the University of California, Berkeley Radiation Laboratory	408
III. New Projects: The King-Sized Experiments	409
A. Background	409
B. The University of Utah Beagle Project	409
1. Origin	409
2. The Next Steps	411
3. The Utah Project Gets Under Way	413
4. Inhalation Aspects	413
5. A Comment on Significance	414
6. The Modus Operandi	415
7. Results at Utah	417
a. Bone Tumors and the Toxicity Ratio	417
b. Effects in Soft Tissue	423

c. Hematology Findings	424
d. Retention and Dosimetry	425
8. Extensions of the Utah Project	426
9. Concluding Comments—Anniversary Volumes	429
C. The Davis Beagle Project	430
D. The Lovelace Project	432
IV. Almost New Projects: Hanford and Los Alamos	434
A. The Hanford Biology Operations	434
1. Immediate Postwar Developments	434
2. Iodine and Sheep	434
3. Miniature Swine	438
4. Tritium	439
5. Radioactive Particles	439
6. Plutonium (Except Inhalation)	440
7. Gastrointestinal Tract	441
8. Studies with the Fetal and Juvenile Mammal	443
9. Therapy	446
10. Symposia and Other Special Publications	447
a. Life Sciences Symposia	447
b. Others	449
B. Los Alamos Scientific Laboratory	450
1. Transition	450
2. Actinide Research	452
3. Tritium	454
4. Fission Products and Other Radioisotopes	456
5. Comment	461
V. Other U.S. Work	461
A. Colorado State University	461
B. New York University Institute of Environmental Sciences	463
C. Oak Ridge Institute of Nuclear Studies and University of Tennessee	463
1. The University of Tennessee-Atomic Energy Commission Farm (UT-AEC Farm)	463
2. Medical Division of Oak Ridge Institute of Nuclear Studies	463
D. University of Rochester	464
E. Other Laboratories and Organizations	465
1. Cornell University	465
2. Oak Ridge National Laboratory	465
a. Biology Division	465
b. Health Physics Division	466
3. Health and Safety Laboratory, New York (Environmental Measurements Laboratory)	466
4. University of California, Los Angeles	466
5. U.S. Atomic Energy Commission, Division of Biology and Medicine; U.S. Energy Research and Development Administration, Division of Biological and Environmental Research; U.S. Department of Energy, Office of Health and Environmental Research	466
6. Federal Radiation Council	468
7. National Council on Radiation Protection and Measurements	468

VI. Work Abroad	469
VII. The Transplutonic Elements	470
A. Introductory Considerations	470
B. Behavior in the Body (Metabolism)	472
1. Absorption	472
2. Tissue Distribution	473
3. Chemical Binding	475
4. Excretion	476
5. Addendum: Distribution and Retention	477
C. Toxicity	478
1. Acute Effects	478
2. Long-Term Effects	479
a. Bone Tumors	479
b. Other Long-Term Effects	480
3. Effective Toxicity	481
4. Comment	481
VIII. Summary and Commentary	482
Note 1	483
References	484

Capsule Chronology^(a)

- 1946** Hanford establishes a Biology Section under Radiological Sciences Division (Parker, Kornberg, et al.).
- 1947** Hanford experiment on radioiodine in sheep begins; a multi-generational project (Bustad et al.). Continued for many years.
- 1947–1960** Work at Berkeley continues on numerous radionuclides by process of “chewing through the periodic table” (Hamilton and Durbin).
 Work on metabolism of ^{90}Sr in rhesus monkey (Durbin at Berkeley).
 Systematic study of lanthanides. Progression of behavior found from lighter to heavier elements (Durbin at Berkeley).
- 1947–1970 (approx.)** Long-term comparative toxicity experiment with mice at Argonne National Laboratory (M. Finkel et al.). A continuation of work begun during war; includes plutonium, radium, uranium, and fission products. Relative effectiveness is a function of dose. Soft tissue as well as skeletal tumors produced.
- 1950–1954** Work with tritium at Hanford. The earliest definitive experiments, including checks on man (Thompson, Ballou, and Kornberg).
- 1950** Utah project is organized. “Founding Fathers” gather, and staff is assembled. Los Alamos takes an active role in development of the project.
 Synthesis of berkelium (Thompson, Ghiorso, and Seaborg at Berkeley).
 Synthesis of californium (Thompson, Street, Ghiorso, and Seaborg at Berkeley).
- 1951 et seq.** Follow-up of Los Alamos plutonium workers begins (Langham, and Shipman; later Hempelmann and Voelz).
- 1952** Synthesis of einsteinium (Ghiorso, Thompson, Higgins, and Seaborg at Berkeley), discovered in products of first thermonuclear test. Kept secret until 1955.
- 1952** First beagle injected at Utah. Eight dosage levels settled on.
- 1952–1964** Long-term experiment at Argonne on ^{89}Sr , ^{90}Sr , and ^{90}Sr - ^{90}Y . Thousands of mice. Evidence for more than one process in tumor production. Ingested doses more effective than expected.
- 1953** Synthesis of fermium (Berkeley team). Same story as einsteinium.
- 1954–1958** Work at Berkeley on ^{223}Ra , the daughter of actinium. One of the few effects studies at Berkeley in the decade after the war (Durbin).
- 1954** Radioactive particles receive attention at Hanford (see chapter 9). Utah conference on plutonium, radium, and mesothorium (2nd Annual).
- 1956** Davis Project initiated; primarily to study effect of ingested ^{90}Sr but with radium injected to establish tie to Utah work. Tied closely to fallout problems. See chapter 13 (Anderson and Bustad; later Goldman et al.).
- Late 1950s** Experiment at Rochester on strontium in rats and monkeys (Tuttle and Casarett). For more on postwar work at Rochester see inhalation chapters.

(a) For inhalation work see chapters 9 and 10.

- 1954 et seq.** Systematic study of comparative metabolism of radionuclides, mostly fission products, at Los Alamos (Richmond and Furchner).
- 1955** Synthesis of mendelevium (Ghiorso et al. at Berkeley).
- 1955** First osteosarcoma in the Utah experiment.
- 1956–1984** Continuous work at Hanford (later Pacific Northwest Laboratory) on gastrointestinal uptake and effects of radionuclides in gut (Sullivan).
- 1958** Synthesis of nobelium (Ghiorso et al. at Berkeley).
- 1958–1984** Effects of age on metabolism of radionuclides. Radiobiology of fetal and juvenile mammal (Sikov at Hanford).
- 1959** Large feeding experiment with ⁹⁰Sr begins with miniature swine at Hanford; see chapter 13 (McClellan and Bustad).
- 1959–1964** Metabolism of strontium in the dog (Norris et al. at Argonne).
Skin tumors found.
- 1960** Miniature swine at Hanford enter the radioiodine experiment.
- 1960s** Metabolism of americium and radiocalcium in the rat (Durbin at Berkeley).
- 1961** Lovelace Project established (see chapter 9).
Ten-year-anniversary symposium of Utah Project (Jee et al. 1962).
Synthesis of lawrencium (Ghiorso et al. at Berkeley).
Retention functions worked out in the Utah beagles.
- 1962** Plutonium studied in swine at Hanford (Bustad et al.).
First Hanford biology symposium is on transuranium elements.
- 1963** Second Hanford biology symposium is on radioiodine.
- 1965** Binding of plutonium to body constituents worked out (Taylor).
- 1965 et seq.** Transplutronics found to be less toxic in general than plutonium.
- 1966** Americium added to the Utah experiment.
- 1967** RBE^(a) of radionuclides in Utah experiment appears to be grossly similar to that found earlier in mice at Argonne.
Importance of liver deposition of plutonium and thorium again surfaces.
- 1967** Fifteen-year-anniversary symposium of Utah Project (Mays et al. 1969).
- 1970** Twenty-year-anniversary symposium of Utah Project (Stover and Jee 1972).
- 1970s** Work at Colorado State University on entry of plutonium via wounds (Lebel, Watters, et al.).
- 1971** Radiostrontium symposium held at Davis (Goldman and Bustad 1972).
- 1971–1972** Review of plutonium in man using primarily the patients injected during World War II (Durbin at Berkeley).

(a) For abbreviations and acronyms, see Appendix D.

- 1973 Definitive reviews of biomedical aspects of plutonium and the trans-plutonic elements. Book edited by Hodge, Stannard, and Hursh. Reviews by Bair and colleagues; Dolphin; Durbin; Ghiorso, Langham, and Healy; Low-Beer; Parker; Seaborg; Stannard; Taylor and Vaughan. (Note: reviews of uranium are contained in chapter 2.)
- 1974 Real differences noted between ^{238}Pu and ^{239}Pu in metabolism and effects (Bair et al. at Hanford).
AEC develops series of in-house task forces on actinides centered especially on adequacy of standards for plutonium.
- 1974 Emphasis on plutonium in gonads (Utah, Los Alamos).
Comparison of plutonium isomers at Hanford (Bair).
- 1975 Twenty-five-year-anniversary symposium of Utah Project (Jee 1976).
- 1977 ERDA sponsors a workshop at Seattle on the actinides. Plans laid for many years.

Chapter 8

Post-World-War-II Research on the Actinides and Fission Products

Overview

This chapter reviews an effort that could easily be a book in itself. In fact, some full-sized books exist that consider only a part of the subject matter embraced by this chapter. Despite efforts to be concise, it must perforce be rather lengthy, even with postponement for later consideration of inhalation toxicology and studies primarily centered on research generated by the problems of fallout from nuclear weapons tests (chapters 9, 12, and 13).

Some of the active laboratories of World War II blossomed forth with major efforts, which were largely extensions of their war work (Extensions and Consummations). Entirely new projects of considerable size were set up to address specific areas of major concern (New Projects: The King-Sized Experiments). Laboratories that were primarily focused on practical or industrial-type problems during the war expanded their horizons so materially that the work was "almost new," even if rooted in their wartime problems (Almost New Projects: Hanford and Los Alamos). Other laboratories in the United States participated to a lesser degree, largely because of involvement in other areas (Other U.S. Work).

Although this book emphasizes U.S. work, since it is a history and not a monograph, it is essential to take up briefly what was going on in other countries, particularly the United Kingdom, France, and the USSR (Work Abroad).

The organization of the chapter is by laboratory in order to permit a connected discourse on how the several groups attacked the problems they chose to focus upon. Each had its own philosophy and approach, even though the ultimate facts emerging were more or less consonant with each other.

One area, the transplutonic elements, is handled differently. Small glimpses of work with the elements above plutonium in the periodic table are seen from time to time in reviewing the individual laboratories. But there was no single effort with the transplutonics comparable to those with plutonium or the fission products. Therefore, it was considered advisable to develop a short overview of the biomedical work done in several laboratories with transplutonics in animals as a final section (The Transplutonic Elements).

Support for biomedical studies of the actinides and fission products was especially strong during the years from 1950 to 1975. It has continued but with diminishing strength into the 1980s. Large experiments were organized and supported because they had to be done. They must be continued to their logical conclusions. This support benefited all areas of radioisotope toxicology and will have, if the lessons learned are heeded, a significant impact on the field of chemical toxicology. For these reasons, and despite the fact that some of the motivation came from the problems of fallout, which many would prefer we had never had to face, I have labeled these efforts "part of a Golden Era."

I. Part of a Golden Era

The wartime efforts had established many basic facts about the behavior and effects of the fission products and the actinide elements. But much remained to be done, particularly in finding the effects of low-level, long-term exposures. While true in nearly all of the areas of interest in this book, these needs were especially evident in the domains of the new dimensions of internal emitter research discussed in the last two chapters.

The explosion of knowledge in the postwar years applied in its way to the research on internal emitter effects and metabolism. The pressures were easing so that mechanisms could be explored in depth along with the more practical needs for low-level and long-term study. While the enterprise got a further boost from the problems attending the development of nuclear power and fallout from nuclear weapons testing (see chapters 11, 12, and 13), it had considerable momentum already from the unfinished business of the war years. This took the form of direct extensions of work already under way and in the organization of new projects to address the chronic toxicity question, with fully sanctioned forays into the exploration of mechanisms (up to a point). We will concentrate on the first two approaches in this chapter and leave some of the more basic considerations for chapters 20 and 21 or, alas, leave them out altogether since they have been very well covered in the published literature. Even with this restriction, we will not be able to examine what was done in anything like the detail accorded some other areas. There has been so much done and so much published that detailed examination would require far too much space. Fortunately, there have been numerous symposia and published volumes so that pursuit of further information is much easier than in some of the other areas pertinent to our objectives. These publications will be referenced at appropriate points.

In terms of both financial support and interest in the biomedical community, these years, 1950 to 1975, were in a way a Golden Era for internal emitter research, as they were for all of radiobiology. Experiments were organized and most will be completed that neither could nor would be undertaken in the 1980s. It is said that the pertinent Congressional Committees even asked the Director of the Division of Biology and Medicine of the Atomic Energy Commission (AEC) if he was sure he had asked for enough money to do what needed to be done! Indeed a Golden Era.

II. Extensions and Consummations

In this section, we will examine research on fission products and the actinides that is clearly a direct extension of wartime experiments or so closely tied

thereto as to be so characterized. Much of this work culminated in the decade of the 1950s and was supplanted by the newly organized or reorganized projects to be viewed in section III.

A. Argonne National Laboratory

1. Relative Toxicity in the Mouse

The comparison of acute lethality of radium and plutonium in rat and mouse at Chicago and Rochester was discussed in chapter 7. No further comparative toxicity work was done at Rochester, but at Argonne National Laboratory (ANL), the standardized radioisotope toxicity experiments^(a) reported early by Brues et al. (see chapter 7) were carried forward by Miriam Finkel and her colleagues. The result was a series of detailed papers in ANL reports and many published documents. Some of these were called "Relative Biological Effectiveness of Internal Emitters."^(b)

One of the most concise reports is that by M. P. Finkel (1956). Here, 6,254 mice contributed data for the twelve isotopes listed in table 8.1. The important characteristics of the isotopes used are shown in table 8.2:

TABLE 8.1. Materials and Range of Doses

Isotope	Range of Doses ($\mu\text{C/gm.}$)	No. of Dose Levels	No. of Mice
Ra ²²⁶	4.170 - 0.0006	14	675
Pu ²³⁹	0.0504 - 0.00004	12	765
Po ²¹⁰	0.097 - 0.00046	9	645
U ²³³	0.10 - 0.001	10	675
U ²³²	0.001 - 0.0001	3	135
Th ²²⁸	0.360 - 0.0066	6	75
Ru ^{106*}	8.94 - 0.57	5	40
Sr ⁹⁰	9.33 - 0.001	12	810
Sr ⁸⁹	7.8 - 0.05	7	352
Y ⁹⁰	28.9 - 4.7	10	103
P ³²	7.36 - 0.01	8	401
Ca ⁴⁵	49.6 - 0.016	10	448
Controls			1,130
Total			6,254

(a) Conceived and designed by Miriam P. Finkel (personal interview, 1978).

(b) This broad use of the term "relative biological effectiveness" (RBE) disturbed some who thought the term should be reserved for comparison of the effects of radiation with different linear energy transfer (LET) values. The usage persists in some segments of the internal emitter literature. However, the International Commission on Radiological Protection (ICRP) and others use the term "equal effectiveness ratio." This author prefers the latter since RBE has a different and earlier specific definition.

TABLE 8.2. Characteristics of the Isotopes Used in the Standardized Radioisotope Toxicity Experiments at Chicago (ANL)

Isotope	Energy (MeV)	Half-Life	Subsequent Radiations	Site of Major Deposition
Ra ²²⁶	4.8 α	1620 yr.	4 alphas within 4 days	Skeleton
Pu ²³⁹	5.15 α	24,300 yr.	(U-235, 7.1 x 10 ⁸ yr.)	Skeleton, liver
Po ²¹⁰	5.3 α	138.3 days	(stable lead)	Reticular tissues
U ²³³	4.8 α	1.62 x 10 ⁵ yr.	(Th-229, 7,300 yr.)	Skeleton, kidneys
U ²³²	5.3 α	70 yr.	5.4 α , 1.9 yr.; 4 alphas within 4 days	Skeleton, kidneys
Th ²²⁸	5.4 α	1.9 yr.	4 alphas within 4 days	Reticular tissues
Ru ¹⁰⁶	0.04 β^-	1 yr.	3.5 β^- , 30 sec.	Skeleton, liver
Sr ⁸⁹	1.48 β^-	50 days	(stable Y)	Skeleton
Sr ⁹⁰	0.54 β^-	28 yr.	2.18 β^- , 64.2 hr.	Skeleton
Y ⁹⁰	2.18 β^-	64.2 hr.	(stable Zr)	Skeleton, liver
P ³²	1.70 β^-	14.3 days	(stable S)	(General), skeleton
Ca ⁴⁵	0.25 β^-	152 days	(stable Sc)	(General), skeleton

In addition to presenting the acute toxicity of many isotopes not ready for presentation at the end of the war years, this work extends into the area of chronic toxicity, especially induction of lymphoid and bone tumors. The acute mortality, expressed as a rate per one hundred mice per twenty-five-day interval, is shown in figure 8.1.

FIGURE 8.1. Relationship between isotope dose and mortality rate in mice. (Redrawn from M. P. Finkel 1956. Reprinted with permission of Radiological Society of North America, Oak Brook, Illinois, copyright 1956.)

Obviously, plutonium, polonium, and even ^{233}U are considerably more effective than ^{226}Ra ^(a), while the beta and beta-gamma emitters are much less effective. This confirms and amplifies the plutonium/radium relationship discussed in chapter 7. The time to 50% mortality showed roughly the same relationship in this more extensive study.

These same data, plotted as a "relative biological effectiveness" factor (see discussion above) by converting the radium curve to unity, are shown in figure 8.2.

FIGURE 8.2. Biological effectiveness relative to radium in increasing net mean mortality rate in mice. (Redrawn from M. P. Finkel 1956. Reprinted with permission of Radiological Society of North America, Oak Brook, Illinois, copyright 1956.)

These figures must be regarded as somewhat tentative since the last animals had not yet died and the experiment was thus incomplete. Nevertheless, it is quite clear that the RBE varies with the mortality rates, a point of importance for extrapolation to the very low doses in human exposure situations. The author gives ratios of mortality at the lowest measured rate of 15(^{239}Pu) : 4(^{210}Po) : 1(^{226}Ra) : 0.07(^{90}Sr) : and 0.02 (^{32}P).

Turning to tumor incidence, we find this influence of dose and time even more clearly evident. The incidence of *lymphoid tumors*, taken again as a rate per one hundred mice per twenty-five-day interval, is relatively low for the bone-seeking elements and much alike except for ^{45}Ca at high doses. But the soft-tissue-seeking alpha emitter, ^{210}Po , assumed considerable importance at

(a) See chapter 2 for further discussion of the $^{233}\text{U}/^{226}\text{Ra}$ story.

about $0.01 \mu\text{Ci/g}$ administered dose, while the soft-tissue-seeking beta emitters such as ^{32}P and ^{90}Y became quite potent generators of lymphoid tumors at doses above about $1 \mu\text{Ci/g}$.

All of this is shown in figure 8.3.

FIGURE 8.3. Relationship between isotope dose and net rate of mortality with lymphoid tumors in mice. (Redrawn from M. P. Finkel 1956. Reprinted with permission of Radiological Society of North America, Oak Brook, Illinois, copyright 1956.)

By contrast, the alpha emitters plutonium and radium increased the rates of bone malignancy at doses in the range of approximately 0.002 to $0.02 \mu\text{Ci/g}$ for plutonium and 0.008 to $0.7 \mu\text{Ci/g}$ for radium (as read from the graphs), while the beta emitters became effective only at high doses. These relationships are shown in figure 8.4.

If an average rate of incidence of ten deaths with bone tumors per twenty-five days per one hundred animals is taken, the effectiveness ratios become $20(^{239}\text{Pu}) : 1(^{226}\text{Ra}) : 0.2(^{90}\text{Sr}) : 0.1(^{89}\text{Sr}) : 0.05(^{45}\text{Ca})$. While not identical with the ratios derived from the mortality data, the complexities of the experiments are such that these must be regarded as more like them than different.

At one of the M. D. Anderson Hospital cancer symposia in Houston, M. P. Finkel presented a summary paper involving some of the same basic data but expanding more upon possible mechanisms of the differences in toxicity of the several isotopes. The paper was published in 1959 (Finkel 1959a). The incidence rates were translated to a probability that the animal will die with a malignant bone tumor. Both the effectiveness ratios and the relationship to dose remain essentially as before, with plutonium clearly the most potent bone carcinogen at low doses and ^{90}Sr and ^{45}Ca the most effective at high doses. A possible explanation is that the alpha particles kill more cells at all dosages, and optimal neoplastic changes thus occur at lower doses of these. The beta emitters by

FIGURE 8.4. Relationship between isotope dose and net rate of mortality with malignant bone tumors in mice. (Redrawn from M. P. Finkel 1956. Reprinted with permission of Radiological Society of North America, Oak Brook, Illinois, copyright 1956.)

contrast may be less effective carcinogens at low doses and also produce less cell killing. Thus, many potentially neoplastic cells are alive when the beta doses finally reach carcinogenic levels.

An effect of dosage pattern is seen with strontium isotopes. This is summarized in the Texas paper but is given in much more detail in a series of ANL quarterly reports, which we will review in the next section.

The importance and behavior of the latent period for cancer induction, a ubiquitous problem in all of cancer biology, was, of course, considered in this long series of experiments at Argonne. The first impression (during the war years) was that the period of latency increased with decreasing dose. With the more extensive data available, the latent period gradually appeared to decrease to about 150 days and to be independent of dose. Indeed, it appeared to be independent of age, of isotope, and perhaps even of species.^(a)

(a) That this is probably not a generalized phenomenon for all forms of cancer is apparent from the masterful review of the pathogenesis of radionuclide-induced tumors given by Casarett at the 1972 Hanford symposium, *Radionuclide Carcinogenesis* (Casarett 1973). There is the puzzle about how to define latent period. The Argonne workers chose to define it as the time between isotope administration and death with a tumor. Later work with serial x-ray studies of the skeleton (to be discussed) requires a different definition. Another view is that there are two periods: (1) the time between the initiation of the carcinogenic process and its expression in some detectable form,

In another 1959 summary paper involving 4,616 mice, Finkel (1959b) presents data for six of the twelve isotopes presented in the 1956 paper. The same general relationships are seen for decrease in average survival time (figures 2 and 3 of the referenced paper) as in the earlier reports.^(a) Tumor expectancy is given instead of tumor incidence. This is based on the number of tumors still to appear in a population divided by the number of animals still alive at any given time—the calculation obviously being done after the data were in. This has the advantage of not being influenced by past events, but the disadvantage that each surviving fraction of the surviving population has less time to live and thus less time to develop tumors. But the parameter can be manipulated to produce an entity called “tumor intensity.”

Using this and other parameters, Finkel concludes that tumor induction may be a more sensitive indicator of radiation damage than mortality. Also, by analysis of the accumulating information on soft-tissue tumors, she suggests that these (e.g., reticular tissue tumors) may be a more sensitive indicator even than bone-tumor incidence.

The toxicity ratios shown, but not discussed in this last series of experiments, appear similar to those found earlier.

In essence, the primary information derived from these long-term experiments is a much strengthened toxicity ratio for plutonium/radium. It also supports ratios for many other isotopes, and provides some leads toward concepts and mechanisms. On balance, the ratios used by Brues at the time of the first Tri-Partite Conference on Internal Emitter Standards in 1949 look reasonably correct with ten years of added perspective (chapter 16).

Because of the ubiquitous problems with endemic disease in the animal colony of the Plutonium Project (old Site B discussed in chapter 2 and Appendix B) and even after the war, Finkel and her colleagues did an entirely new radium experiment during the 1950s and 1960s. This was discussed briefly in chapter 2 (see Finkel, Biskis, and Jinkins 1969). The new experiment can be plotted on the same mortality scale as used in the earlier work, i.e., fraction of mice bearing at least one malignant bone tumor against accumulated radiation dose at one hundred days. In the reanalysis of both sets of data by Durbin and Wrenn (1975), discussed in chapter 2, the slope of the curve for the new experiment is 0.043% tumors/rad versus 0.012% tumors/rad in the 1953 experiment.

and (2) the time between the delivery of the effective radiation dose and the completion of the pathologic processes required to start the carcinogenic response. In practice, the so-called latent period may often include both of these. But techniques of detection and measurement will have a sharp influence. Age must have an effect if the radiation dose is given late enough in the life span. Later Argonne work addresses all of these factors plus a lot of information on the role of cofactors (e.g., viral components in the etiology). But it is significant that the results of one of the largest and most complete studies in the mouse up to its time indicated relative independence of the latent period from several important factors usually expected to have an important influence. Finkel (1981) prefers to view the phenomena as illustrating only that the probability of getting bone cancer increases with increasing dose.

- (a) The same animals were involved in these two reports. The difference in total numbers of mice is due to omission of a few high-dose groups. The isotopes were not all studied simultaneously because of space limitations. Radium and plutonium were done together; the uranium isotopes were done together. Polonium was done separately.

Apparently the clearing out of endemic infection saved the animals for bone tumor development! Whether or not the toxicity ratio would be altered under these different laboratory conditions cannot be stated and probably will never be known. The simplest procedure is to assume that all incidence curves at the chronic level would be moved in the same direction in the new animal care environment, and their relationship to each other would remain roughly the same. This emphasizes the extent to which intercurrent murine infections have been a cross to bear in long-term work, and the importance of having the best and constant quality of animal housing and care.

In summary of these experiments, the following generalizations can be made:

1. The toxicity ratio is a function of the magnitude of the carcinogenic effect. At very low doses, ^{239}Pu appears to be only about five times as potent as ^{226}Ra , while ^{232}U is about twice as effective. At these same low doses, ^{233}U is one-half as effective as ^{226}Ra , while ^{90}Sr and ^{45}Ca are 1/125 and 1/1000 as effective, respectively. These are all on the basis of bone-tumor development. In the high-dose domain, ^{90}Sr and ^{45}Ca become much more effective; indeed, these produced the maximum number of tumors, probably because the alpha emitters have a much higher component of cell killing.
2. The toxicity ratio for mortality is not identical to that for carcinogenesis, but it is roughly comparable.
3. There is an indifference range where effects are no greater than in controls. No linear function could be made to fit the incidence data, especially at low doses. The authors could not conclude that a threshold existed without an even larger number of animals.
4. The latent period for cancer induction in these experiments seems to be independent of isotope and size of dose, but this is not certain.
5. Soft-tissue tumors were induced by all of the isotopes but especially by ^{210}Po , ^{90}Y , and ^{32}P . These tumors may turn out to be as sensitive an indicator as bone tumors.
6. The injected-dose basis is used in this work because the authors feel that more information is needed before radiation dose can be calculated with confidence.

2. Radiostrontium in Mice

As part of the large Argonne effort with mice, particular emphasis was placed on work with both ^{89}Sr and ^{90}Sr , and the ^{90}Sr - ^{90}Y couplet. The results were seen first in Quarterly Progress Reports (Finkel, Brues, and Lisco 1952, 1954; Finkel, Lisco, and Brues 1954, 1955; Finkel et al. 1956), and somewhat later in published papers (Finkel, Biskis, and Scribner 1959; Finkel, Biskis, and Bergstrand 1960; Finkel, Bergstrand, and Biskis 1960, 1961; Finkel, Jinkins, and Biskis 1964). This was a major effort involving thousands of mice to whose care Dr. Finkel, along with a dedicated staff, devoted herself personally. Although nominally a part of the relative toxicity series, these went well beyond its needs. In part, the effort was enhanced by the problems of fallout and, in part, by the need for careful dissection of the relevant parameters.

There are many progress reports and a few additional published documents beyond those cited in the bibliography. But those cited give the flavor of what was done, and going much further would carry us too far beyond studies to be regarded as direct extensions of the war work.

It will be noted that the cited ANL documents concern ^{89}Sr , while all of the publications refer to ^{90}Sr . The Argonne group places little emphasis on this difference, and it must be concluded that, except for some temporal aspects, the differences between the two isotopes were small.

Two major questions were addressed in these experiments: (1) the influence of dosage parameters brought about by giving single compared to divided doses, and (2) mechanistic studies, including general and special pathology.

In the comparison of dosage regimes, it is pointed out that dose fractionation does more than modify dose rate. Deposition is apt to be more uniform in bone on a split-dose regime since there are many more deposition sites available. By dividing the doses among regimes of one, five, or twenty injections and the isotope doses over a suitable range, many combinations of doses and dose rates could be obtained. The results are complex, but a few points can be extracted.

1. Life shortening was, in general, less with multiple doses, but the difference was small at low doses. This is illustrated in figure 8.5 where expectation of life in the mouse given by Finkel, Biskis, and Bergstrand (1960) and Brues (1949) is plotted against dose. (These data were recalculated by Stannard, Blair, and Baxter [1964].)

FIGURE 8.5. Life-span shortening with multiple doses of ^{90}Sr . (Redrawn from Stannard, Blair, and Baxter 1964, based upon data of Finkel et al. over several years. Reprinted with permission of Academic Press, Inc., Orlando, Florida, copyright 1964.)

2. The incidence of malignant bone tumors is a more complex function of dosage regimes. This is illustrated in figure 8.6, taken from Finkel, Biskis, and Bergstrand (1960). In general, the incidence of osteogenic sarcoma was higher at most times after the single injections. But the difference is very small at the highest dose and reverses itself at about 375 days at the middle dose. At the low dose of most interest to radiation protection, the greater effectiveness of single doses is quite clear. Whether this difference resides in the presence of recovery from the low-LET beta radiation, mode of deposition, isotope removal rates, or some combination of these cannot be determined from the information at hand.

FIGURE 8.6. Incidence of osteogenic sarcomas in mice as a function of time and dosage pattern of ^{90}Sr – ^{90}Y . (Redrawn from Finkel, Biskis, and Bergstrand 1960. Reprinted with permission of University of Minnesota-Twin Cities, Minneapolis, Minnesota, copyright 1960.)

3. Tumors of the blood-forming tissues depend in a complex way on total dose and fractionation. For example, a dose of 1 $\mu\text{Ci/g}$ was most effective in producing lymphocytic neoplasm if given in a single injection, least effective if divided into twenty parts. At 0.5 $\mu\text{Ci/g}$, there was little difference between a single dose and five fractions, but twenty fractions were less carcinogenic than either a single or five. At 0.25 $\mu\text{Ci/g}$, both five-part and twenty-part fractionations were more effective than a single injection. This contrasts with the mortality and bone-tumor-incidence figures.
4. Explanation of the findings in (2) and (3) was considered to lie in the presence of at least two, perhaps more, processes. One may be a direct effect of the radiation; another may be indirect (part of the multifactorial causation of cancer?) or abscopal.
5. The authors propose that many of the data are consistent with the idea that initial dose rate is an important, perhaps controlling, factor.
6. There are definite strain differences in both the incidence and the location of tumors.

Other work of the Argonne group showed that autoradiography could be used for dosimetry as well as microlocalization of the isotopes (Marshall, Rowland, and Jowsey 1956; Rowland and Marshall 1959; Marshall and Finkel 1960). Also, serial x-ray examinations permitted early detection of tumors long before anything could be palpated. This was extended at both Argonne and other laboratories into considerable formal study of the kinetics of tumor growth.

The consequences of continuous ingestion of ^{90}Sr were not quite as expected (Finkel, Biskis, and Bergstrand 1960; Finkel, Bergstrand, and Biskis 1960). Strontium is reasonably well absorbed from the gut, i.e., about 30% of administered dose. Yet, animals fed a ^{90}Sr - ^{90}Y mixture (the ^{90}Y is essentially unabsorbed) from conception showed surprisingly few tumors except at quite high doses. This was despite some life-span shortening. Those sarcomas that did appear were later as well as less numerous than after injection. This was considered a dose-rate effect. Also, there was little evidence that neonatal and young animals were significantly more sensitive than adults on the basis of the parameters measured.

3. Other Work at Argonne

Several other studies in the decade and a half after the war fall into the category of this section.

a. Lethality and Carcinogenicity of Radiostrontium in Other Species

Other species, such as dogs and cats, were occasionally added to the strontium studies by the Finkel group and described in some of the publications cited. A quite complete report of work with the dog is contained in the symposium, *Biomedical Implications of Radiostrontium Exposure*, held at the Davis, California, laboratory in 1971 (Finkel et al. 1972). This work started in 1947. It differed from the studies at Utah, which we will review in the next major section of this chapter, by including multiple injections from birth as well as single injections. There were 147 dogs with 29 controls in a complex mixture of intravenous, subcutaneous, and placental dosage regimes and from 1 to 259 injections. The results were qualitatively comparable to the results with mice, except for a greater incidence of tumors of bone other than osteogenic sarcomas such as hemangiosarcomas, fibrosarcomas, and chondrosarcomas. The incidence of

these was up to one-fourth in the dog versus low and not related to dose in mice. Strontium-90-yttrium-90 is absorbed in the larger bones of dogs, and thus a given injected dose produces more rad than in the small bones of mice.

The primary idea of this work was to help scale from mouse through dog to man. The conclusions are that, with proper corrections for size, retention, etc., dog and mouse are probably equally sensitive, young animals are not more sensitive than adults, and a dose distributed nonuniformly in space and time is more oncogenic than a uniformly distributed dose. These last two conclusions are somewhat contrary to general radiobiological thinking and should receive further scrutiny.

b. Metabolism of Strontium

Decker and Norris developed a device for measuring the gamma radiation from ^{85}Sr in the dog (Decker and Norris 1959). This was used, along with an ionization chamber set up for rodents, to investigate strontium metabolism as a function of age (Speckman and Norris 1964; Decker, Kaspar, and Norris 1964). The ^{85}Sr was produced at the laboratory by deuteron bombardment of rubidium chloride. The animals in the first study were rats and a few mice, in the second study dogs.

The power function so characteristically found to describe retention of bone seekers in experiments at Chicago seemed to describe the data for mice injected at 271 days and rats injected from 207 days onward. Injection at earlier times gave curves with changing slope up to a time that varied with the age at injection. All the retention curves in the rodent showed identical slopes after about 100 days. Mathematical treatment of the data is indulged in.

In the dog, only a modified power function could describe the retention data. Strontium retention became progressively less up to an age approaching ten years. But the difference was small after five years. Possible mechanics are discussed in somewhat more complex fashion than we saw in the handling of the radium data (chapter 1).

Brues et al. made a special effort to look at the retention and metabolism of ^{90}Sr in soft tissues since tumors were arising in these, and, in their view, the subject had been neglected (Brues et al. 1967). This work was part of an international symposium concerned with fallout problems that we will examine presently. But it can be considered also an extension of the Plutonium Project work. The object was determination of dosage, which they put in terms of microcurie-days. Particular emphasis was placed on blood and testis. There were two experiments: one in which the strontium was accompanied by its yttrium daughter, the other in which the ^{90}Sr had been freed of ^{90}Y before injection. The $^{90}\text{Y}/^{90}\text{Sr}$ ratio was different in different tissues and at different times. Liver had the highest ratio for the longest time. The work indicated that dosage calculations to soft tissues would not be simple.

Other kinetic studies compared plutonium and yttrium in blood, liver, and skeleton in the rat (Schubert et al. 1950); relative rates of transfer of barium, radium, and strontium between blood and bone (Lloyd 1968), this time including data on man, rabbit, and rat. The first was aimed primarily at further understanding of the role of radiocolloids and of a diffusion-controlled mechanism in uptake by bone, which obediently followed diffusion kinetics except for an initial, very rapid process, which was not kinetically like diffusion. The second work bore more on the discrimination factors seen in many physiological processes, which we will review in chapters 13 and 15.

c. Locally Deposited Isotopes

Even during the war years, the Chicago group was interested in induction of tumors of the skin by placement of beta-irradiating sources of different geometries. In the postwar period, this was extended to studying local effects of an insoluble beta emitter placed under the skin of the back or in a limb. Finkel et al. (1956) used a suspension of $^{91}\text{YPO}_4$. Local lesions included greying of the fur, epilation, ulceration, skin carcinoma, and other tumors near the site of injection. In addition, osteogenic sarcomas appeared at the highest dose, as did diseases of kidney, liver, and lung (including lung tumors). Many of these, however, were due to endemic infections in the colony, but some might have been due to radioisotope absorption from the injection site. The injected doses were quite large.

This initial study was followed some years later by a series issued by Brues and collaborators under the title *Mechanisms of Carcinogenesis*. The central theme was to define the conditions under which tumors are induced by local irradiation (Brues et al. 1966–1969; Brues et al. 1967). They also used chemical carcinogens. In so doing, they learned much about the transfer of isotopes from injection sites, cell dynamics preceding and during the carcinogenic process, role of various physiological variables including hormonal controls, etc. Further discussion would carry us beyond the scope of this chapter. Suffice it to say that this progression is fairly typical of how the programmatic war work gradually metamorphosed into studies of fundamental mechanisms. The same is true of Miriam Finkel's work, which became more and more oriented to fundamental cancer biology after the early 1960s.

d. Plutonium at Argonne National Laboratory in the Postwar Years

Whereas Chicago was the major center along with Berkeley for plutonium research of all kinds during the war years, it eased up greatly in the postwar era, particularly in biology and medicine. Other laboratories were picking up the thread with large-scale biology experiments. The primary contributions from ANL came from the relative toxicity work already described (a not inconsiderable effort) and occasional publications and papers at symposia. One of the papers concerned a study of plutonium toxicity in nine hundred mice (Finkel and Biskis 1962). This gives in detail the story of the plutonium segment of some of the earlier, more general, publications.

The findings are by now a somewhat familiar story, but the doses went lower than in the early work, and the analysis of the findings is most complete. Liver changes were quite common (fatty and parenchymatous degeneration, inclusion bodies, but no malignant tumors). Osteogenic sarcomas appeared in 66 of 886 mice studied. There was a maximum in average tumor expectancy at a dose above the median dose, but not the highest, i.e., $6.3 \mu\text{Ci/kg}$, while the dose range was 0.04 to $40.6 \mu\text{Ci/kg}$, given intravenously. The tumor expectancy was linear to dose only on a logarithmic plot.

An interesting summary and indication of how the various end points move about with dose is found in table 8.3, taken from the cited reference.

Because of the interest in environmental contamination in the 1960s and 1970s, Finkel dusted off and reanalyzed some experimental data obtained during the war years concerning transfer and effects of plutonium in mothers' milk and via the placenta. This was presented at one of the Sun Valley symposia held by the Utah group. The primary animals were mice, but a pregnant cat and a

milk goat also participated. The nuances of the experiments are wide. Some animals received their plutonium by the placenta only; some by both placenta and milk; some by milk only. Some of the rats received goat's milk containing plutonium, others received plutonium-citrate by stomach tube. The results (Finkel and Kisieleski 1976) indicate that a relatively low percentage of the plutonium entering the animal is incorporated, e.g., 0.019% in rats, 0.11% in mice, and about 0.28% in cats. Yet, because the plutonium so acquired "was avidly retained in bone" (p. 57), a significant quantity can be accumulated. For reasons that are not clear, considerably more was incorporated when it came from plutonium-milk rather than plutonium-citrate. One of the cats developed two osteogenic sarcomas 7.5 yr after ingestion of ^{239}Pu in milk. These were considered to be radiogenic. No deleterious effects were found in the several hundred mice receiving prenatal and/or neonatal exposure.

4. Comment

There were scattered other studies at Argonne that could be considered extensions of the war work, e.g., late effects of cesium in mice, plutonium metal implants, kinetics of bone seekers in dogs, etc. Most of these tie more closely to work done as a result of the fallout problems. They will be reviewed subsequently.

B. University of California at Berkeley

1. Extensions of Research on Fission Products and Heavy Metals

In the immediate postwar period, despite the changes in personnel mentioned in chapter 6, Hamilton and his staff continued tracer studies with fission

products by going on to the less abundantly produced elements. Durbin relates that this process was known affectionately among the staff as "chewing our way through the periodic table" (Durbin 1976), remarking that next to the 60-in. cyclotron the periodic table held the greatest fascination for Joe Hamilton. By 1959-1960 most of the radioisotopes from fission and many others of interest had been studied. Attention turned to problems there had not been time to attack during the war years. This resulted in the following:

a. Laboratory Report on Localization of Cerium-144

A University of California Radiation Laboratory (UCRL) report was issued on localization of ^{144}Ce in the skeletal tissues of fetal rats (Asling et al. 1957) with special concern for the site of microscopic localization. Initial binding appears to be in the organic matrix.

b. Study of the Distribution of Radioisotopes of Some Heavy Metals

This was comprehensive study of the distribution of radioisotopes of some heavy metals in the rat in which the cyclotron-produced isotopes were used strictly as tracers for learning the fate of small quantities of commonly known as well as lesser-studied (at that time) heavy metals (Durbin, Scott, and Hamilton 1957). Included were cadmium, mercury, iridium, thallium, tin, lead, niobium, tantalum, molybdenum, tungsten, technetium, rhenium, ruthenium, osmium, rhodium, palladium, and platinum. These were administered either carrier-free or at high specific activity by intravenous or intramuscular injection, or occasionally by gavage. Organs of primary deposition were cited along with total retention, organ retention, and the associated biological loss constants. There is also a brief review of the toxicological literature for each element in this very useful series.

On the basis of the distribution, absorption, and excretion, the authors divide these eighteen heavy metals into four groups:

1. those absorbed readily from the gastrointestinal tract with marked and prolonged retention in liver and kidney (cadmium and mercury in valence state +2)
2. those absorbed relatively slowly, retained transiently in liver and kidney, but for prolonged periods in skeleton (iridium, tin, lead, niobium, and tantalum in valence states +2 to +4 and without complexing agents)
3. those excreted promptly and nearly completely in urine (molybdenum, tungsten, technetium, rhenium, osmium, and ruthenium administered as complex ions)
4. those showing fairly rapid and nearly complete excretion in both urine and feces with some transient retention in kidney, spleen, and liver (rhodium, iridium, palladium, platinum in valence states +2 to +4).

This work is an important indication of how the general approaches and techniques of the Manhattan Engineer District (MED) can be expanded and benefit a much larger area of toxicology and biochemistry.

c. Work on Metabolism of Strontium-90 in Monkeys

This work was begun as a natural extension of the tracer work on radiostrontium done during the war. There was much talk of repeating the rodent work with longer-lived species (and after the fallout problems arose of extending it to long-term effects). Durbin and her colleagues, with help and encouragement

from Joe Hamilton, decided to see if metabolism of radiostrontium in primates resembled that seen in rodents and in the early dog studies. The first reports concerned the rhesus monkey, a most heroic choice of subject for metabolism studies requiring quantitative collection of excreta, if possible.^(a)

An early report was given at a Department of Defense symposium on the shorter-term biological hazards of a fallout field (Durbin et al. 1956c, 1957). Even though the paper is labeled "Preliminary," it gives a full picture of what was under way, as indicated by the abstract reproduced below:

Adult rhesus monkeys eliminated 56% of administered Sr^{90} , compared with 28% of Ca^{45} , in the urine during the first 10 days after intravenous administration.

The Sr^{90} concentration in the vertebrae was found to be reasonably representative of the skeleton as a whole in two animals whose skeletal distribution of Sr^{90} was studied. Successive amputation of caudal vertebrae is therefore recommended as the simplest and safest method of acquiring information on long-term skeletal retention of Sr^{90} in valuable animals with long life spans.

Average half times for skeletal retention of Sr^{90} were calculated for an adult male, 470 days, and for an adult female that had experienced three closely spaced pregnancies, 315 days.

Half times for skeletal retention of Sr^{90} of 155 and 195 days were calculated for the first 10 months of life of two offspring born to an injected mother.

One infant monkey retained an average of 18% of Sr^{90} administered daily by mouth for 13 weeks, whereas six adolescents retained on the average less than 5% of a daily dose during the same period of time.

A measurable amount of Sr^{90} , 23.5 dpm/g bone ash, was found in the skeleton of an uninjected control animal.

Placental transfer from a mother with a fairly well-fixed skeletal burden of Sr^{90} amounted to about 3% of the Sr^{90} content of the mother's skeleton at term.

The Sr^{90} concentration in milk samples from an injected female taken shortly after the birth of her second offspring (402 days post-injection) was three to four times the Sr^{90} level of a plasma sample taken a few days later.

(Durbin et al. 1956c, p. 173)

While the abstract does not state it, the answer to the basic question was that the metabolism of ^{90}Sr in the monkey followed qualitatively the pattern seen in other species. The biological half-time is longer than in the early rat experiments (about 400 days instead of >200 days), but not greatly different from more recent double-labeling work the authors did with ^{90}Sr and ^{45}Ca in rats (i.e., 350 days in the rats versus 400 days in the monkey). Calculation of half-time in man on the basis of relative life expectancy did not agree with the then-accepted value used by the ICRP. Longer-term studies were needed.

The retention equation was taken up further in a "Work in Progress" report by Durbin et al. in *Radiology* (1959) and a paper at the Second International Conference on the Peaceful Uses of Atomic Energy (Durbin and Jones 1958). In both instances, and in both rat and monkey, exponential rather than power functions fitted the data best. (Compare the Argonne National Laboratory studies above.) The turnover equations of rat and monkey were sufficiently alike to suggest that the information from the monkey may provide a reasonable

(a) Anyone not familiar with the pernicious excretory habits of this species should visit the nearest zoo and return with admiration for the laboratory workers who devote years to research with them. At Berkeley, liaison must have been good, for the reports identify the animals by name.

estimate for the human skeleton. However, the times are still relatively short (eight months in rat and four years in monkey). Hence, continued observation was considered necessary. This was done by addition of new monkeys and observations over a significant portion of this species' thirty-year life span. Some of the results were presented at the third International Radiation Protection Association (IRPA) Congress (Durbin et al. 1973). They will not be dwelt upon here except to say that the monkey still looked like a reasonable model for alkaline earth metabolism over long periods. This research and further new work at Berkeley with other species are more appropriately a part of chapter 13 (research stimulated by the problems of fallout) than a continuation of the World-War-II studies, although such separation is obviously somewhat arbitrary.

2. Systematic Study of the Lanthanides

In view of the important similarities and differences seen in general behavior of the lanthanides compared to the actinides, it is not surprising that the postwar extension of the work at Berkeley in biology and medicine included systematic study of both. We will examine the actinide research in a later section but give a capsule summary of the lanthanide (lanthanon) rare earth group research here.

For this work, the lanthanons were considered to fall between barium (atomic number 56) and hafnium (atomic number 72) (i.e., lanthanum through lutetium). Durbin et al. (1955) present in a UCRL report an informative capsule history of the lanthanide group, development of separations techniques, and the *raison d'être* and technical details for the extensive study carried out in the early postwar years. Many of the heavier elements not studied in the war work were added. The isotopes used were ^{140}La , ^{144}Ce , ^{143}Pr , ^{147}Pm , ^{153}Sm , $^{152,154}\text{Eu}$, ^{159}Gd , ^{160}Tb , ^{166}Dy , ^{166}Ho , ^{169}Er , ^{170}Tm , ^{175}Yb , and ^{177}Lu . Many were prepared as very pure stable isotopes by Frank Spedding's group at the Iowa State University and irradiated in the new high-neutron flux reactor at Idaho Falls to produce radioisotopes of high specific activity. Others came from the Oak Ridge Reactor or from Drs. Seaborg and Thompson at Berkeley. Thus, we see a marked departure from using almost exclusively the products of the 60-in. cyclotron at the Crocker Laboratory.

The results and technical details, but without some of the historical perspective, are in a published paper by the same authors (Durbin et al. 1956d).

The work corrected many of the defects of the war work, which had variable amounts of carrier present, sometimes quite low specific activities, and less than rigid control of age, sex, and strain of the animals. Also, the size of the experimental groups could be increased to increase statistical validity.

The earlier work used chlorides or nitrates of the elements concerned, and absorption was frequently poor. For the new work, the more soluble citrate complexes were employed. The intramuscular route of injection was used, aiming to avoid formation of insoluble radiocolloids frequently seen after intravenous injection. The oral route was used for some experiments.

Absorption from the intramuscular site was fairly complete, with the exception of a few instances involving the larger quantities injected. Absorption from the gut was quite low.

The skeleton was the most important long-term deposition site for all members of the group, and it appeared that combination was largely with organic matrix (i.e., bone protein) rather than bone mineral, thus expanding the autoradiographic findings of the war. Microscopically, the deposition in bone was largely on endosteal and periosteal surfaces and near small blood vessels in compact

bone. There were progressive increases in skeletal deposition with progression from lighter to heavier elements. Liver accumulates the lighter lanthanons as the primary deposition site, while it is only a secondary repository for the heavier members of the group.

The relative deposition in liver and skeleton is shown in figure 8.7A and B for selected members of the series.

There is a clear progression in behavior from the lighter to the heavier elements. Obviously, much of the skeletal content at longer times is due to its avid retention compared to liver. Other soft tissues accumulated less and lost it more rapidly still.

FIGURE 8.7A. Retention of several radionuclides in liver: (Redrawn from Durbin et al. 1956a.)

FIGURE 8.7B. Retention of several radionuclides in skeleton. (Redrawn from Durbin et al. 1956a.)

Excretion is also a function of place of the element in the series. Two routes participate: kidney to urine and liver to gastrointestinal tract via bile. The lighter elements are lost rapidly in feces by mobilization from the liver, while the heavier elements are excreted largely by kidney, at least initially. The UCRL report (1956b) and paper (1956a) by Durbin et al. give the specifics.

In a paper prepared for the landmark conference on rare earths in biochemical and biomedical research held at the Oak Ridge Institute in October 1955, Durbin et al. (1956a) presented time studies of the tissue distribution of the lanthanons given by intravenous injection. Cesium-144, $^{152,154}Eu$, ^{160}Tb , and ^{170}Tm

were employed as citrate complexes. The primary thrust of this work was, in addition to the distribution pattern, the mode of transport of microgram amounts of the lanthanons in the blood stream. This bore especially on the role of radiocolloids and aggregates, a problem of much interest to researchers with radioisotopes at that time (and seemingly somewhat neglected in present-day work). This paper, as well as the entire conference, is replete with important information and correlations on the rare earths in biology and medicine.

Interestingly, the tissue and excretion kinetics in this intravenous work were quite similar to those seen in the earlier work using intramuscular injection, something of a negation of the concerns that led to the original choice against intravenous injection.

An overview of this extensive work is provided by Durbin et al. (1955) by using much the same classification as the chemists, i.e., light, transition, and heavy lanthanons. The key findings are quoted below as an excerpt from report UCRL-3066.

1. The light lanthanons (lanthanum through samarium). Deposition was primarily in the liver and skeleton, 50% and 25% of the administered dose respectively. Elimination from the liver (presumably by way of the bile duct to the gastrointestinal tract) was quite rapid with a half time of about 15 days. Two months after injection the skeleton retained about two-thirds of its initial deposition; there was no further elimination from the skeleton during the subsequent eight months.
2. The transition lanthanons (europium and gadolinium). Deposition was more nearly equal in liver and skeleton, 30% and 40% of the administered dose respectively. Excretion was both fecal and urinary.
3. The heavy lanthanons (terbium through lutetium). Deposition was mainly skeletal, 55% to 65% of the administered dose. Elimination from the skeleton was slow with a half time of approximately 2.5 years. Excretion of extraskelatal heavy lanthanon occurred within the first two weeks after injection and was almost entirely urinary. (Durbin et al. 1955)

Before leaving the rare earth group, a few comments on the motivation for this large effort are in order:

1. The group presents an orderly progression of chemical properties based upon electronic structure. Their chemistry and methods for isolation have presented many challenges, now made less challenging by the advent of ion-exchange resins. Exploration of their behavior in biological systems posed problems of significance to understanding of which chemical properties are most important to metabolism of these elements.
2. The prevailing valence state is +3, somewhat in contrast to many of the elements in other groups of significance to internal emitter toxicology.
3. There are a large number of rare earth elements, and many occur naturally in living organisms.
4. A few rare earths assumed considerable importance in atomic energy development.
5. Many rare earths are represented in the products of nuclear fission and may be environmental contaminants.
6. Some rare earths have properties of localization in particular areas of bone and appropriate radiation energies and half-lives to be candidates for

therapeutic uses. (For example, radiogallium, a close relative of the rare earths, was studied extensively at the Oak Ridge Institute for Nuclear Studies, as we shall see in chapter 20.)

3. Iodine and Related Elements

Major background for the war work at Berkeley was, as described earlier, prewar work with radioiodine. During the war, iodine was studied as one of the fission products, and its significance to the organism was immediately appreciated. In the postwar years we are now examining, a veritable deluge of studies came from Berkeley on iodine, particularly comparisons between iodine and astatine, an alpha emitter that seeks thyroid tissue. This involved much more than the metabolic researches we have been looking at. It is part of the history of nuclear medicine, part of the history of the fallout-stimulated researches. It is considered, somewhat arbitrarily perhaps, that the story of iodine and its relatives can be treated in a more connected way using a different format, where several lines of investigation can be viewed simultaneously. Thus, the Berkeley work in this field will be reserved for chapters 10 and 13 and, to a lesser extent, chapter 20.

4. Actinide Research in the Postwar Years

The Berkeley group did relatively little postwar actinide research that can be tied as closely to the war work as the experimental studies on lanthanons and alkaline earths just described, or the large effort with iodine and astatine to be described later. But there were very significant contributions. Some were additional laboratory experiments, particularly with the transplutonics. Others were enormously useful general reviews and syntheses of information from many sources. We will look first at some of the new experimental work.

In the international symposium, *Delayed Effects of Bone-Seeking Radio-nuclides*, a festschrift celebrating the fifteenth anniversary of the Utah Project, held in Sun Valley, Idaho, in September 1967, Durbin, Jeung, and Williams (1969) presented data on the behavior of ^{241}Am and ^{45}Ca in the skeleton of Charles River rats. Contrast of the retention curves, which were sums of exponentials, occurred between different bones and between the radioelements. The authors identify the segments with physiological processes, identified by autoradiographic, tracer, and histologic means. The loss curves for americium had fewer components than those of calcium, and there were indications that it did not participate in exchange reactions in bone, in contrast to the alkaline earths and alkali metals. It was retained indefinitely in bones like rib and mandible, which do not experience net mineral loss in old age. In addition, redistribution could be correlated with specific processes in bone. As a supplement to the life-span tracer studies, a background of growth and senescence in the female rat was provided. The animals showed no radiation-connected pathology at the levels used. A kinetic model of americium metabolism was derived for the rodent.

Further studies were seen primarily in papers presented at meetings, e.g., Durbin, Williams, and Jeung (1961, 1972). Each concerned primarily elaboration of metabolism and mechanisms and used the monkey, the cynomolgus monkey in the latter work—a more tractable beast than the rhesus monkey. In addition to these, there were several unpublished (e.g., Durbin, Jeung, and Williams [1972b]) studies that came to light in Durbin's monumental review of the transplutonium elements to be discussed presently.

A somewhat generalized study using examples of each major group of bone-seeking elements, including plutonium and americium, was published by Asling et al. in 1952. This was an autoradiographic study of the deposition and behavior of several elements in the costochondral junction in the bones of rats, a site that contains periosteal tissue with osteogenic potential, yet not immediately adjacent to bone. The elements used were calcium, strontium, promethium, plutonium, and americium, all in high specific activity. Details of localization are given, and they confirmed, in general, ideas from earlier work.

The second aspect of the Berkeley postwar work with the actinides consisted of a series of enormously useful, scholarly, and sophisticated correlative reviews. These are pertinent to all aspects of the ongoing biomedical research with the actinides and will be considered as we review the specific subjects. But we should see them once all together. Therefore, they are listed below with a few comments on what they contain:

1. Metabolic Characteristics within a Chemical Family. P. W. Durbin, *Health Phys.* 2:225-238 (1960). A broad review of seventy elements: alkali metals, alkaline earths, lanthanides, and actinides; Groups IV, V, VI, VII, and the platinum metals. Properties that determine biological behavior are reviewed.
2. Distribution of the Transuranic Elements in Mammals. P. W. Durbin, *Health Phys.* 8:665-671 (1962). A review of chemical properties of both actinides and lanthanides and comparisons of their biological behavior.
3. Plutonium in Man: A Twenty-Five Year Review. P. W. Durbin, Report UCRL-20850 (June 1971). A reanalysis of the data from the injected patients described in chapter 7.
4. Plutonium in Man: A New Look at the Old Data. P. W. Durbin, chapter in *Radiobiology of Plutonium*, B. J. Stover and W. S. S. Jee, eds. J. W. Press, Salt Lake City (1972). Also report UCRL-20850 (no date). A retrospective study primarily of the patients described in chapter 7 in light of the new knowledge.
5. Plutonium Deposition Kinetics in the Rat. P. W. Durbin, M. W. Horovitz, and E. R. Close, *Health Phys.* 22:731-741 (1972). Development of a kinetic model and its implications for mechanisms.
6. Metabolism and Biological Effects of the Transplutonium Elements. P. W. Durbin, chapter 18 in *Handbook of Experimental Pharmacology*, Vol. 36, Hodge, Stannard, and Hursh, eds. Springer-Verlag, pp. 739-896 (1973). A comprehensive compilation and analysis of all of the biomedical data on transplutonics, which had hitherto been scattered throughout the world literature. In itself, it is worth the rather heavy price of the book for anyone really needing to know.
7. Behavior of Plutonium in Animals and Man. P. W. Durbin, Plutonium Information Meeting for an ad hoc subcommittee of the Advisory Committee on Reactor Safeguards, Los Alamos, New Mexico (January 1974a). A comprehensive review.
8. Transfer of Plutonium from Soil to Plants: A Review of the Problem. P. W. Durbin, Report UCID-3689 (September 1974b).
9. Plutonium in Mammals: Influence of Plutonium Chemistry, Route of Administration and Physiological Status of the Animal on Initial Distribution and Long-Term Metabolism. P. W. Durbin, *Health Phys.* 29:495-510 (1975). Current concepts of plutonium metabolism reviewed.

10. Survival, Causes of Death and Estimated Tissue Doses in a Group of Human Beings Injected with Plutonium. R. E. Rowland and P. W. Durbin. In *Health Effects of Plutonium and Radium*, W. S. S. Jee, ed. J. W. Press, Salt Lake City, pp. 329-341 (1976). Adds dose calculation to the review of the plutonium patients.
11. A Summary of Actinide Biological Research, 1943-1977. P. W. Durbin. Workshop on Research Needs in Actinide Biology. DOE Conference-770491 (1978b). Appendix A (1978b). A wide ranging history; Appendix B, Actinide Biological Research in Progress (1976-1977), (Durbin 1978a). A review for purposes of evaluating all programs.

5. Radium-223, The Daughter of Actinium

The interest in actinides at Berkeley included tracer-level metabolic research with ^{227}Ac (Hamilton 1954, p. 23) and, for the first time, an effects study using a daughter product, ^{223}Ra . This isotope is an alpha emitter of 11.2-days half-life and has a series of short-lived alpha-particle descendants with energy totaling 20 MeV, plus two beta emitters with an average energy of 0.5 MeV each. It was given intramuscularly as a citrate complex (Hamilton 1954, p. 26; Durbin et al. 1958).

Radium-223 proved to be highly toxic acutely, quite in contrast to the longer-lived radium isotopes, which are surprisingly ineffective acutely. The mean lethal dose in thirty days was about $0.05 \mu\text{Ci/g}$ body weight, compared to about $1.6 \mu\text{Ci/g}$ for ^{226}Ra in adult rats. A full account is given of hematological effects and gross as well as some microscopic pathology. The possible reasons for the difference in acute toxicity between ^{223}Ra and ^{226}Ra are given. Obviously, the initial dose rate with ^{223}Ra is much higher than with ^{226}Ra . But, in general, dose-rate influences are small with alpha emitters and when present seem more to favor increased effectiveness of protracted doses. Differences in the blood-forming centers were marked, e.g., very little ectopic myelopoiesis in the ^{223}Ra animals, while with other radium isotopes there were many centers of blood-cell regeneration, which might tide the animals over the acute radiation syndrome phases.

This interesting work, while quite complete in the UCRL reports, seems never to have been published in the open literature.

6. Crocker, Donner, and the University of California, Berkeley Radiation Laboratory

The internal emitter metabolism and toxicology work became part of the Donner Laboratory (or so the by-lines in the publications stated for a while after the transition). Donner had a long history of interest in radioisotopes, as tracers (Jones et al.), in nuclear medicine (John Lawrence et al.), and superb work with the variety of high-energy sources available in the Radiation Laboratory (Tobias et al.) "on the hill." In due course, the internal emitter toxicology research was moved to a laboratory building also on the hill behind the Berkeley campus in the University of California, Berkeley Radiation Laboratory area. While no longer identified as a separate enterprise by the appellation "Crocker Laboratory," the group continued to have a fair degree of autonomy. Also, the new location provided more adequate facilities for care of animals.

Besides their inherent value and their usefulness to the plutonium Project workers and their successors, the metabolic behavior data from

these postwar studies, as well as the earlier data, were fed directly into the work of Committees II of the ICRP and the National Council on Radiological Protection and Measurements (NCRP), as we shall see in chapter 16. And it is all part of the foundations of nuclear medicine—which was where the interest began in the first place in the late 1930s.

III. New Projects: The King-Sized Experiments

A. Background

“One thing that cannot be bought in biological research is time.” John R. Totter, chairman of the AEC’s Division of Biology and Medicine, made this remark toward the latter part of the AEC years at the twentieth anniversary celebration of the University of Utah Laboratory of Radiobiology (Totter 1972). The reader must already have become aware of that axiom for internal emitter research in the chapter on radium. We have felt the problems, perhaps subliminally, in our reviews of work with rodents that seemed to die of pneumonia, or the diseases of aging, at just about the time the changes of most interest, such as cancer, might have turned up at relatively low levels of exposure. We saw in chapter 2 that it took eleven years in a single experiment to establish some of the really long-term effects of inhaled uranium.

Many attempts have been made recently to speed up the process by use of cells in tissue culture or other surrogates for the long-term effects. But in 1947 these were unknown—and even now we are not sure we have a reliable substitute. Today the field of chemical toxicology is faced with learning about the long-term effects of thousands of chemicals. Whether or not they can find a way to cut some corners in time, it is essential that all interested in chemical toxicology take a lead from the enormous efforts put into radiation toxicology.

There was a mass movement in the early days of the AEC toward setting up experiments with long-lived animals in sufficient numbers to do each job as an entity and to avoid expensive repetitions. This was true of both the problems of external radiation and of deposited radioisotopes. They included eventually the Argonne National Laboratory and the Hanford works of General Electric as well as the Universities of California, Michigan, Rochester, Utah, and Wisconsin. At Oak Ridge, the “megamouse” experiment was set up for study of genetic effects of radiation, and it is still going at well past several million mice. (Obviously, genetic work of the type needed could be done only with a short-lived species. But this was one of the few exceptions to the trend toward larger, longer-lived animals). The Department of Health, Education and Welfare joined the procession by sponsoring a large experiment using external radiation with dogs at Colorado State University.

The granddaddy of them all, at least for internal emitter research, and in some respects the most uniquely organized, was the project at the University of Utah at Salt Lake City. We will examine its genesis and accomplishments in some detail in the following section.

B. The University of Utah Beagle Project

1. Origin

This project had its origin at Los Alamos. The memory of what went on at the Chalk River Tri-Partite Conference on Permissible Doses lingered in the minds

of people like Wright Langham, whom we met in chapter 7, and of Tom Shipman, the Health Division leader at Los Alamos. Work with plutonium and radium in mice had led to tentative adoption of a new plutonium standard that would have shut down Los Alamos.^(a) Yet, all concerned knew that extrapolation to man from the work with rodents had many problems. The year 1950 saw these problems lead to the organization of an entirely new and very large project.

First let us look at the setting as seen in an extract from a letter from Thomas L. Shipman, M.D. to Dr. Shields Warren, director of the Division of Biology and Medicine of AEC, dated June 19, 1950:

At the conference on tolerances which was held at Chalk River in October of last year, it turned out that tolerance figures for plutonium were decided principally on the basis of some work which Austin Brues had done using several hundred rats and mice and six dogs. The work which Dr. Brues did was excellent, and we have no desire to cast any doubts on what he has done. I am certain that he will agree, however, that the situation produced a decision of rather far reaching consequences which was based on a foundation that was shaky simply because there was not enough experimental evidence.

Rats and mice are excellent animals to use for certain purposes, but all of us are aware that in studies with radium, plutonium and other bone-seekers, they have certain very definite disadvantages. In the first place, the long bones of the rodent do not unite at maturity and they just continue to keep growing until they die. Furthermore, these animals have a distressing way of dying of pneumonia at just about the time they are ready to develop bone tumors, pathological fractures, and other evidences of damage from the material under study. This has required that they be given rather massive doses of plutonium or whatnot, if significant effects are to be observed. As should be obvious, we are no longer much interested in the effects of massive doses; we must concern ourselves with the long-term effects of doses in the vicinity of the tolerance level. The dogs that Dr. Brues used, six of them, were, as I understand it, the survivors from an experiment to determine lethal doses. They too had received doses far in excess of the range in which we are interested.

To cast even more doubt on the validity of our existing data, is the current indecision as to the actual toxicity of radium itself. It was assumed that this matter was pretty well nailed down, but recent information about mesothorium has found the subject pretty much up in the air. We have little choice but to go back and start at the beginning. Here again the use of animals larger than rodents is essential; rodents excrete about 85% of their radon; while man excretes 40-50%. Dogs should resemble man far more closely in this respect, as well as having a skeletal weight which in proportion to total body weight would far more closely approximate man.

Further along, Dr. Shipman emphasizes the keen interest of the Los Alamos people in getting the new project started. But it soon became apparent that Los Alamos was not a very suitable site for such an operation. Los Alamos was still a very restricted area and a very expensive place to operate. The plan was for about two hundred dogs to receive plutonium and radium by injection and by inhalation in a separate experiment.

Almost immediately, Austin Brues was brought into the discussion. After all, he had supplied the original data (along with his colleagues such as Miriam Finkel, as we have already seen in chapters 6 and 7, and earlier sections of this

(a) The reasons it did not are reviewed in chapter 16.

chapter). And since there were strong reasons to include ^{226}Ra , Robley Evans was soon invited and became an enthusiastic participant.^(a)

Shields Warren, the director of the new AEC Division of Biology and Medicine, was not hard to convince of the need for such an experiment. That year records many letters, as well as several meetings, between him and the principals. Wright Langham took the major initiative for following through and presenting the plans in greater and greater detail to potential sponsors as the project took shape.

But it was a project without a home, indeed without a director or personnel. It had only Langham, Brues, Evans, and, to a lesser extent, Shipman and Shields Warren to urge that it be done and help it in every possible way. But when people with that much interest and clout get excited about a new enterprise, something is likely to happen. And it did. John Z. Bowers, who had been in the AEC Division of Biology and Medicine, accepted the post of Dean of the Medical School at the University of Utah and agreed to see if the project could be placed there. The advantages of being on a university campus, and part of a medical school, were stressed for their importance in obtaining consultative assistance and in providing a home for the new personnel. Bowers persuaded some key department heads in the school that it was a good idea, and the project acquired a home.

The details of assembling space, facilities, and personnel are told partly in some of the volumes commemorating the several anniversaries of the project, most completely in the paper by Betsy and Clarence Stover in the twentieth anniversary volume (Stover and Stover 1972). But the full story can be gleaned only from the correspondence, minutes of meetings, and personal reminiscences of those concerned. Many of the original personnel are still available to help anyone interested in further specific details.

2. The Next Steps

Langham, Brues, and Evans—who were later to be part of the group called “The Founding Fathers” of the Utah Project—got right to work on detailed plans for the experiments. The dog was the instant and unanimous choice. Early it was thought that the American foxhound would be a good choice, but it soon became evident that adequate supplies of this animal would be a problem. Meanwhile, in other quarters, the advantages of the beagle had stimulated interest, and their similarities to man in the areas of most interest to the project cast the die.

A history of the beagle strain and of its adaptation to research was given by Rehfeld, Blomquist, and Taylor (1972), also at the twentieth anniversary meeting. Among the advantages were the unusual uniformity present in the breed, made even greater by the fact that a breeding colony was to be established; equality in stamina; adaptability (as a pack dog) to living in a colony; a relatively docile, if occasionally stubborn, disposition;^(b) and easy liaison with humans.

(a) The problems of the radium standard occasioned by the realization of the special toxicity of mesothorium are probably somewhat exaggerated in the Shipman letter quoted. As we saw in chapter 1, they did as much to help explain some anomalous results in the human as to raise questions about the validity of the standard. But there was no question that ^{226}Ra had to be the bench mark in such an experiment.

(b) This was usually an advantage in the highly routine existence of the research colony, but not so helpful when a change in routine was attempted.

Since the details are important not only to our review of the development of the Utah project, but to many of the other postwar experiments, two excerpts from the pertinent papers are given below. The first is the abstract of the Rehfeld, Blomquist, and Taylor (1972) paper at the twentieth anniversary symposium:

Throughout its history of at least 500 years the beagle has been fostered and developed as a small, hound-type hunting companion, primarily in France and the British Isles. Americans started importing beagles from the British Isles in the 1870's and since that time the breed has steadily grown in popularity as a hunting, companion, and research dog. Its history as a research animal extends back only to the comparatively recent year of 1950. Starting at that time, the Radiobiology Division at the University of Utah has had a major role in pioneering the in-laboratory breeding and care of beagles for research. This laboratory has produced 1427 beagles since 1950 with a total of 32 animals acquired for breeding purposes; each of the 103 of the laboratory-bred animals produced one or more young to contribute to this total. The descendants of 18 acquired and 21 laboratory-bred animals were favored in selection of successive generations of breeding stock. All of the 21 dogs were related to the original 18, so a large proportion of the colony dogs are directly related to them. Although a large number of the laboratory-bred beagles are inbred, in a majority (80.3%) of these, the inbreeding is less than that which would result from one sibling mating. This colony of beagles was started in 1950 at a time when there were no large research dog colonies in existence and soon became a model colony within a prototype physical facility. (Rehfeld, Blomquist, and Taylor 1972, p. 47)(a)

The second is a list of scientific advantages from a paper by Mays et al.: "Advantages of the Beagle in Long-Term Radiobiological Studies" (1973, p. 110):

1. Skeletal similarity to man.
2. Importance of jaw syndrome induced in man and beagles, but not rodents.
3. Relevant radiographic information.
4. Osteosarcoma location.
5. Possible differences in shape of dose-response: Rodents vs. large mammals.
6. Unique sex difference in bone sarcoma induction: Mice vs. humans and beagles.
7. Growth dynamics of osteosarcomas.
8. Liver retention of ^{239}Pu .
9. Advantage in obtaining sequential blood samples in beagles.
10. Corticosteroid production similarity between man and beagle.
11. Transaminase and alkaline phosphatase similarities between man and beagle.
12. Advantage of larger organ size in radionuclide distribution studies.

Bustad and colleagues also extolled the virtues of the beagle (and he was a pig man!) in another paper at the twentieth anniversary symposium (Bustad et al. 1972).

Not mentioned in these summaries is the fact that this breed has a very low normal incidence of bone tumors, i.e., osteogenic sarcomas, and of most of the other clinical entities of importance to internal emitter toxicology.

The "Founding Fathers" also occupied themselves with questions of what elements to use, what doses to employ, and what route of entry. Plutonium-239 and ^{226}Ra were the original elements at issue. Robley Evans soon convinced

(a) Not mentioned is a large colony at Cornell University developed mainly for other types of work. The colony at the University of California, Davis, was developed shortly after these.

everyone that the radium data could not be useful for comparison to man unless the toxicity of mesothorium was known in the dog. Thus, mesothorium (^{228}Ra) and radiothorium (^{228}Th), the alpha-emitting decay product of ^{228}Ra , entered the plan. The elements were to be as nearly pure as possible.

There was much debate over dosage levels. A pure arithmetic progression seemed unlikely to cover the range without having to use too many levels. A geometric progression might place too much emphasis on the low levels where little was expected to happen. (This was actually incorrect. Effects occurred at even the lowest levels of plutonium, and new, still lower levels had to be introduced later.) The progression adopted resembled one suggested by George Sacher at Argonne: 1:9:40:83:175, thus giving larger ratios at the lower levels where uncertainty was the greatest.

The anchor points were to have level 1 equivalent to 10 times the accepted maximum permissible level for radium, equivalent to $0.1\ \mu\text{Ci } ^{226}\text{Ra}$, and the maximum at 1,750 times the bench mark. The doses for the other elements were determined from the best estimate of the toxicity ratio from the work described in chapters 6 and 7.

Finally, it was decided to forget about imitating field or industrial exposure situations and do an experiment with the least possible uncertainty regarding initial dose—i.e., intravenous injection of the elements complexed with citrate to avoid, if possible, problems with radiocolloids.

3. The Utah Project Gets Under Way

The first contract between the AEC and the University of Utah became effective July 1, 1950. But Dr. Bowers did not arrive until November, although some staff had already been hired (e.g., Betsy Stover, Garth Westenskow). A veterinarian, Dr. Robert C. Bay, joined the group soon after Dr. Bowers's arrival, and it was fast apparent that the only realistic course was to first establish a breeding colony to supply experimental animals.

In due course, a physicist (Marvin Van Dilla) and a bone histologist (James Arnold) arrived, followed by several veterinarians, a radiologist, hematologist, etc., either full or part-time. We will meet these people in our review of the results.

On the administrative side, Dr. Bowers handled the necessary interactions with the university, while in Washington, Dr. Warren and his special assistant, Dr. Walter Claus, saw to the financial and planning aspects from AEC's viewpoint. In a sense, these three, Bowers, Claus, and Warren were founders too, perhaps "founding uncles" or "rich uncles" rather than "Founding Fathers." Their portraits introduce the twenty-fifth anniversary volume. And there were others, like H. D. Bruner who helped at the AEC level somewhat later on, and who, we will see, had considerable influence at the Washington level on the planning for all radioisotope toxicity experiments. Also at headquarters, Dr. C. W. Shilling, Deputy Director of the Division, shouldered responsibilities for seeing the ideas implemented by Congressional appropriations.

Temporary kennel facilities gave way to the first real kennel for the breeding colony in March 1952. The first beagle to be injected received $3.05\ \mu\text{Ci } ^{239}\text{Pu/kg}$ intravenously on June 24, 1952. The project was officially launched.

4. Inhalation Aspects

In the early plans, it was proposed that a portion of the animals be exposed by inhalation since this was, of course, the likely route of entry. It was not intended

to be very extensive. The intratracheal injection route was considered seriously. But the Los Alamos people had no facilities, nor did they wish to do the necessary planning and building. Eyes turned toward Rochester as the project with the most experience with inhalation work. Harold Hodge, who had much to do with the uranium inhalation work, as we saw in chapter 2, was contacted and invited to meet with the planners. For some reason he was not free to attend, but Drs. Henry A. (Harry) Blair, director of the University of Rochester Atomic Energy Project, and William F. (Bill) Neuman, one of Hodge's right-hand men, did get out to a meeting in the desert. Although they went with little enthusiasm for a new project, the needs impressed them, and a promise of help of some sort came soon afterwards. In fact, as usual, Rochester thought they could fit it in without major additional expenses if a few month's delay were not crucial. Actually, except for some crude experiments done at Rochester and Chicago during the war with burning wires, and some important pioneering work at Berkeley, no one was really prepared to purposely put up aerosols of highly dangerous radioactive materials. Rochester had to fashion an entirely new program, as we will see in chapter 9. But the promise was made and eventuated in Newell Stannard's becoming director of the Radioactive Inhalation Section at Rochester. This episode also resulted in Harry Blair's becoming a member of the Advisory Committee for the Project, an expanded version of the "Founding Fathers."

Meanwhile, Bowers had settled in at Utah. At some time after they were well into operation, he decided that they needed an inhalation chamber there to help with inhalation studies pertinent to the uranium miner problems of the Colorado Plateau. Duncan Holaday, who was stationed in Salt Lake City, had been trying to get help, as we saw in chapter 3. John Bowers decided to try a small foray into the inhalation field and bought a chamber using some funds from a National Institute of Health grant (Stover 1980).

A few exposures were made, and some work was done with ^{233}U , but the expertise needed for successful inhalation toxicology work was apparently not present, or the group had too much else to do. The chamber was sold back to Rochester. So far as this author can ascertain, no formal reports appeared.

5. A Comment on Significance

Before continuing further, we must pause to realize what a unique phenomenon in scientific research this project represented. So far as this author knows, this was the first occurrence in peacetime of a contract between a university and a government agency for a *specific* long-term study, at least in the biological sciences. It was most unusual in having the plans essentially laid out ahead and a powerful advisory group exerting control down to details of dose levels, numbers of animals per group, numbers of controls, etc., even before the personnel had been assembled. Quite the antithesis of the conventional academic research operation! Yet it worked! The credit goes, in part, to the unusually perceptive individuals who saw the needs and realized planning must be in-depth before anything was started. There could never be a repeat. The staff was vigorous, keen, and well able to do collaborative research. This included the original staff and later joiners in the form of graduate students who finished up and joined the ranks (e.g., Jee, Mays).

But I think much credit goes also to the management and attitude of AEC's Division of Biology and Medicine. Their long-term support was essential. Yet,

they managed to achieve all primary objectives while allowing major degrees of freedom in an atmosphere of mature cooperation between partners in an important enterprise. And this was the story at other similar projects too.

An appropriate and interestingly original summary of what was done and how it was done appears in the parable-style paper entitled "Genésis" given by Walter Claus at the twenty-fifth anniversary symposium (Claus 1976). This is reproduced in its entirety as note 1 at the end of this chapter.

6. The Modus Operandi

It was obvious that the injections had to be staggered, since there was not room for all of the animals planned at any one time. The result was a sort of unit approach with groups receiving a single element and their controls starting out together. This could work because of the extraordinary uniformity of the animals and of the conditions.

Each animal was treated as a patient in a well-run hospital, even better, because the complete pedigree of each was known in some detail. There were routine operations that can be seen best in the summary of the first ten years published by Dougherty et al. (1962b). These extended from standardized procedures for preparing an animal to enter the experiment (at approximately 1.4 yr of age) through regularly scheduled clinical and x-ray examinations, to the elaborate and complete post-mortem work-ups. No one can complain that this experiment concentrated too much on cancer as an end point—which some do.

The dogs were confined to stainless steel metabolism cages for one week prior to and for three weeks after injection for the collection of urine and feces. This aided in the estimates of retention and reduced contamination of the outdoor runs. There were interim excreta collections over four-day periods throughout. In addition, in-vivo counting was done where feasible, using a modification of the Los Alamos liquid scintillation counter called "K-9," or a modification of it called "K-9, Bark II."^(a) At autopsy, tissues were analyzed radiochemically. Radon in expired air was measured in the ^{226}Ra animals and thoron in the mesothorium dogs. Thus, retention equations could be derived as a composite from several sources of information.

In table 8.4, the injected doses and numbers of dogs at the end of the first decade are shown. There were many intermediate stages, of course, in reaching this point.

The reader will note that a new isotope, ^{90}Sr , had been added, resulting, of course, from the problems generated by fallout from nuclear weapons testing. Also, some lower and intermediate dosage levels appear. These were inserted as it became apparent that the original plans needed modification to lower levels and some intermediates for certain elements. By virtue of these, the total number had gone from the earlier estimates to over four hundred dogs.

Level 1 was the bench mark, determined from ^{226}Ra by the relation:

$$\frac{10 \times 0.1 \mu\text{Ci } ^{226}\text{Ra}}{70\text{-kg Standard Man}} = \frac{0.0143 \mu\text{Ci } ^{226}\text{Ra}}{\text{kg of Dog}}$$

(a) This picturesque terminology has been attributed to Betsy Stover, the project's principal radiochemist.

or, assuming 25% retention, this becomes:

$$\frac{1}{0.25} \times \frac{0.0143 \mu\text{Ci } ^{226}\text{Ra}}{\text{kg of Dog}} = \frac{0.057 \mu\text{Ci } ^{226}\text{Ra}}{\text{kg of Dog}}$$

which would be the injected dose equivalent to ten times the maximum permissible burden in man of $0.1 \mu\text{Ci}$ of ^{226}Ra .

The other levels have the following relationships to level 1:

Level	Relation to Level 1
0.2	1/9
0.5	1/3
1.5	2x
1.7	3x
2	6x
3	18x
4	54x
5	162x

Level 1 for elements other than ^{226}Ra was based on retention factors characteristic of that element as described by Dougherty et al. (1962a,b) or as later modified.

TABLE 8.4. Injected Doses and Numbers of Dogs^(a)

Dose Level Code	Injected Doses ($\mu\text{Ci/kg}$)					Number of Dogs

It will be noted also that there are twelve controls for each radioisotope for a total of sixty. There was a considerable polemic in the early years over how many controls there should be. A statistician named E. Brandt took part in the early planning and concluded that many fewer controls (i.e., fifteen) would be

adequate. Statistically he was correct, and it was important that space should be concentrated on experimental animals. But the advisory group was concerned. They could visualize how controls would have to follow along in time with their specific injected group and how unexpected losses to disease might reduce the number of controls dangerously. Also, much depended on knowing a lot about the untreated population. So they overrode the statistics, and on the basis of intuition as much as rigid proof made the control group larger and decided that litter mates should be distributed into isotope and control groups. This turned out to be a good plan, although strictly speaking it exceeded the numbers needed for statistical validity, if all went well.

Dr. Bowers left in 1955 to go to the University of Wisconsin as dean of the Medical School, and Dr. Thomas Dougherty took over direction of the project. It became associated with the Department of Anatomy, of which he was chairman, where it remained until Dr. Dougherty died in 1979. Graduate students like Webster Jee and Charles Mays finished their degrees and joined the group. Indeed, they became anchor men, and both, especially Jee, assumed temporary directorship after Dr. Dougherty's death. While there has been some turnover, the staff remained remarkably stable, as needed for successful prosecution of such an experiment. The data began to accumulate in enormous quantities. Yet, reports kept flowing, not only from the main experiment, but from special studies individual staff members could do as their interests dictated. We will review the results very briefly in the section to follow.

7. Results at Utah

The information from this very large project is, of course, impossible to capsule without distortion or omission of many important contributions. This is especially true of the contributions the work has made to basic biological science. Fortunately, in-house reports have been regular and complete and publications most adequate. Particularly useful are the book-sized reports of symposia held approximately each five years (e.g., Dougherty et al. 1962a and subsequent volumes). Since these have been, particularly recently, international in scope and very well organized, their contents provide not only summaries of the Utah results, but a chance to assimilate what was going on worldwide and how the Utah work fitted into the entire field. In addition, semiannual and annual reports presented regular updates of the work as well as numerous special studies.

Americium-241 was introduced in 1966, partly to have a transplutonium element in the scheme, and partly because of its importance as a decay product of ^{241}Pu . (a)

a. Bone Tumors and the Toxicity Ratio

The first dog to die as a result of an osteosarcoma was also the first animal injected at the highest level of ^{226}Ra . The date was October 1955, not much more than three years after the injection. The first osteogenic sarcoma in the plutonium group was also at the highest level. The date of euthanasia was

(a) The plutonium produced in high flux reactors contains more of the heavier isotopes of plutonium, and ^{241}Am became of importance as a potential contaminant. The Utah project, however, continued throughout with "old-fashioned" plutonium from a generous supply made available by Wright Langham.

July 1956. These early occurrences presaged the first general finding: the incidence of bone tumors would be beyond expectations in the planning. Lower dose levels would be needed. This was done as indicated earlier, with both more steps and lower levels.

The complete experiment as it existed in the twentieth year is shown in table 8.5A and B. Table 8.5A shows the doses, and table 8.5B shows the numbers of animals. Note that the controls had to be increased for ^{239}Pu and ^{226}Ra because of the new levels, bringing the total controls to 80 and the total

number of animals to 616. Quite a change from a simple five- to seven-year experiment with "about 200 dogs" to study the plutonium/radium toxicity ratio!

Since the original purpose of the Utah Project was determination of the empirical ratios of toxicity of these several elements as compared to ^{226}Ra , let us look immediately at how it came out. Remember that it takes many years to accumulate reliable long-term toxicity information in an animal with a normal life span of fifteen years or more.

At the 1967 symposium at Sun Valley, Idaho, Mays et al. (1969) presented a fairly complete résumé of the findings to date. The survival times versus dose were presented graphically, and the RBE(a) relative to ^{226}Ra was given in much the same way as the data for rodents presented earlier in this chapter. They are reproduced here as figure 8.8A and B.

FIGURE 8.8A. Survival time versus dose for osteosarcoma beagles (March 1967). Each point is the average for the osteosarcoma dogs in an injection level. Connecting these points forms dose-survival curves for all nuclides except ^{90}Sr , for which the dose-survival curve lies between the limits shown by arrows. (Redrawn from Mays et al. 1969. Reprinted with permission of University of Utah Press, Salt Lake City, Utah, copyright 1967.)

The radiation dose was calculated as that to one year before death on the assumption that the tumor had been initiated a year before it killed the animal. The survival figures refer only to animals dying with osteogenic sarcoma, the principal cause of death.

A complete roster of the animals is given in a table in the cited publication along with a set of RBE values based on three criteria: rad at one year, at one year before death, and at death, for each element. These values are a function of the dosage level, much as we saw for the mouse earlier in this chapter. The data for strontium are quite tentative since that element was added to the experiment relatively late, and data were far from complete.

(a) See discussion of this terminology on page 387, footnote b.

FIGURE 8.8B. RBE for death with osteosarcomas in beagles (March 1967) showing the effectiveness of ^{239}Pu , ^{228}Th , and ^{228}Ra relative to ^{226}Ra . That of ^{90}Sr is less and decreases further at long survival times. (Redrawn from Mays et al. 1969. Reprinted with permission of University of Utah Press, Salt Lake City, Utah, copyright 1967.)

For illustration, let us take the RBE values (i.e., toxicity or equal effectiveness ratios) for death with osteosarcoma eight years after injection using neither the highest nor the lowest dosage level. As calculated by Mays et al., these values are $^{226}\text{Ra} = 1$, $^{239}\text{Pu} = 6$, $^{228}\text{Th} = 8$, $^{228}\text{Ra} = 2.5$, and $^{90}\text{Sr} = 0.07$ to 0.24 . Comparing these to the ANL data on the mouse and the MED work on mouse, rat, and dog indicates a rather surprising agreement. Interestingly, ^{228}Th is the most effective in producing bone tumors at all but its lowest level, where it is comparable to ^{239}Pu . (See discussion of thorium in chapter 4.)

Ranges for the equal effectiveness ratio relative to ^{226}Ra over all three criteria and all five dose levels are: $^{239}\text{Pu} = 1.0$ at level 5 and dose to death; to 15 at level 1 and dose at 1 yr; $^{228}\text{Th} = 4.8$ at level 1 and dose to 1 yr, to 21 at level 2 and dose to death; $^{228}\text{Ra} = 2.4$ at level 2 and dose to death, to 6.5 at level 3 and dose to 1 yr; $^{90}\text{Sr} = 0.57$ at level 5 and dose to death, to >0.06 at level 5 and dose to 1 yr.

Of particular interest is the fact that the highest RBE for ^{239}Pu is at level 1, in the area of greatest interest for radiation protection purposes; and the surprisingly high effectiveness of ^{228}Th . The range of ratios is not large considering the many variables involved; and it is close enough to the earlier data to greatly strengthen any decisions regarding allowable exposures based upon the earlier work; yes, even the Tri-Partite Conference!

The prime cause of death with all of these elements was osteogenic sarcoma. Plutonium-239 seemed to retain its place as the most effective of all at low doses (i.e., long survival times), and the bone-surface seekers were, as a group, more effective than the volume seekers, just as in the mouse and rat.

The doses and dose rates in the beagle skeleton calculated to twenty years are shown in figure 8.9A and B for level 1 using the data accumulated through 1967.

FIGURE 8.9A. Dose-rates in 1-level beagle skeletons. The 1-level injections were $0.0157 \mu\text{Ci } ^{239}\text{Pu/kg}$; $0.0152 \mu\text{Ci } ^{228}\text{Th/kg}$; $0.0505 \mu\text{Ci } ^{228}\text{Ra (MsTh)/kg}$; $0.0621 \mu\text{Ci } ^{228}\text{Ra/kg}$; or $0.571 \mu\text{Ci } ^{90}\text{Sr/kg}$. The dose-rate for ^{239}Pu remains fairly constant; that for ^{228}Th decreases primarily because of radioactive decay; that for $^{228}\text{Ra (MsTh)}$ increases initially due to the build-up of its alpha-emitting daughters—but it subsequently decreases because of radioactive decay and biological excretion; that for ^{228}Ra decreases because of biological excretion, while that for ^{90}Sr decreases because of both biological excretion and radioactive decay. (Redrawn from Mays et al. 1969. Reprinted with permission of University of Utah Press, Salt Lake City, Utah, copyright 1969.)

As time passed, attention was directed more toward understanding of mechanisms and expressing toxicity as a risk. Indeed, the quoted 1969 paper seems to be the last from Utah in which the ratio of toxicities is presented in the original form. (It was quoted by others long afterwards.) As a gauge of how the continuation of the experiment over additional years might influence the results, let us look at a report from 1979 (Mays et al. 1979). Using the points in the low-dose realm, the risk of osteosarcoma from ^{239}Pu was 5,200 bone sarcomas per 10^6 beagle-rad. The figure for ^{226}Ra was 320 bone sarcomas per 10^6 beagle-rad. The ratio is 16.25, assuming linearity of incidence to dose.

For the 1980 meeting of the International Radiation Protection Association, Mays and M. P. Finkel prepared a paper comparing alpha particles and beta

FIGURE 8.9B. Cumulative doses in 1-level beagle skeletons. (Redrawn from Mays et al. 1969. Reprinted with permission of University of Utah Press, Salt Lake City, Utah, copyright 1969.)

particles, with special emphasis on low doses and low risks. This bore especially on ideas gradually developing that the RBE rises with decreasing dose. When the results for ^{226}Ra and ^{90}Sr in Miriam Finkel's CF1 mice were compared with the accumulated data for the same elements in the beagles, the RBE clearly did rise as dose decreased. The relationships are shown in table 8.6 and figure 8.10.

TABLE 8.6. Bone Sarcoma RBE of ^{226}Ra Versus ^{90}Sr

Species	Incidence (%)	^{90}Sr β -particles (rads)	^{226}Ra α -particles (rads)	RBE (α versus β)
Beagles	66.7	9360	1900*	5
	38.5	8600*	1100	8
	16.7	7940	480*	17
	8.7	5500*	210	26
Mice	86.4	6500*	6420	1
	81.0	6300	4400*	1.4
	79.1	6200*	3640	2
	62.2	5500*	2040	3
	43.3	4600*	1190	4
	21.2	3700*	614	6
	23.4	3800*	480	8
	18.7	3500*	383	9
	13.6	3310	280*	12

FIGURE 8.10. Relative biological effectiveness of alpha-particles from ^{226}Ra and retained daughters, relative to beta-particles from ^{90}Sr and its daughter, ^{90}Y . The RBE increases as dose decreases, both in beagles and in mice. The effect is mainly due to decreased effectiveness per rad in bone-sarcoma induction by beta-particles at low doses and low dose-rates. (Redrawn from Mays and M. P. Finkel 1980.)

The change in RBE is largely related to the change in effectiveness of the ^{90}Sr from lower to higher doses. In fact, the situation is much like the classic picture of low- versus high-LET external radiation sources.

The dental health of the beagles was followed assiduously and maintained well. Specific effects, beyond those connected with general oral health, which was not the best in this colony, appeared with ^{226}Ra , ^{228}Ra , and ^{228}Th . Excessive tooth loss was noted early (Taylor et al. 1961). Altered tooth and jaw structure appeared quite early too, followed by bone tumors (Dougherty et al. 1962b). These changes were comparable qualitatively to those seen in the radium dial painters and called "radium jaw" (chapter 1). See also Jee and Arnold (1960).

Marked gingival changes occurred also (Taylor et al. 1962). These included ulceration, infection, and other changes, again similar to those seen in the dial painters. These results are of special interest since rodents did not, in general, exhibit such marked deterioration of oral structures.

b. Effects in Soft Tissue

The deposition of plutonium and thorium in rodent liver has already been discussed. It was confirmed in the dog.

At the 1967 symposium, Taylor et al. (1969a) summarized soft tissue tumors in the population. Bile duct tumors, but no frank liver tumors, occurred in eight of

the animals receiving ^{239}Pu ; despite localization of the plutonium in other parts of the liver. Necrosis in liver was marked throughout the experiment.^(a)

Intraocular melanomas appeared in seven of the animals receiving ^{226}Ra or ^{228}Ra . (Remember the peculiar ocular changes reported in animals receiving radium, even in the MED days.)^(b) There was a sinus carcinoma in one dog receiving plutonium, one receiving ^{226}Ra , and one receiving ^{90}Sr . If a real finding, this casts doubt on radon as the prime causative agent for the sinus tumors in the dial painters. There were cancerous disturbances in the hematopoietic tissues as expected. But surprisingly these did not seem to be radiation-induced. The incidence of hemic and lymphoid tumors was significantly higher in the controls than in the irradiated groups. (This is not true in beagles receiving ^{90}Sr by feeding, as we shall see in a later section.)

At about the same time, kidney damage termed "radiation nephritis" appeared in the high-level ^{228}Th dogs.

Taylor et al. mentioned the occurrence of a "wide range of benign and malignant growths" in soft tissue, which were "clearly" a normal phenomenon and not caused by the deposited isotopes. The Utah workers were in fact so sure that these changes were not related to the deposited radioisotopes that they excised many such growths "before they could become serious clinical problems." In this respect, the dog work differs from the rodent work, in which treatment of any kind was characteristically withheld. Only in a population whose normal aging and disease behavior is very well known can the experimenter have the courage to intercede with treatment—another tribute to the planning of an ample control population and the presence of hundreds of similar dogs in other colonies about the country.^(c)

c. Hematology Findings

In the ten-year report (Dougherty et al. 1962b), early depression of white cell counts was general at all levels. At the lower doses, return to normal occurred to a greater or lesser degree. Thorium-228 caused more profound and more sustained depression of blood-cell formation at higher dose levels than did any of the other elements. The platelets followed the lymphocyte pattern in general, while the effect on red cells varied more among the radionuclides. In general, there was an early transient anemia, but only at later times was there progressive and serious anemia, and this only in the high-level dogs. Thus, reduction of circulating blood cells and damage to the blood-forming system do not seem to be sufficient in themselves to cause death at the levels of interest to this work.

- (a) Recently, the incidence of liver tumors in other experiments has led some investigators to speculate that liver changes may play a more central role in the toxicity of these elements than the original Utah dog experiments indicated. This requires more information since many of the effects are from Thorotrast, which may involve a factor of chemical toxicity. (See chapter 4 for further discussion and an update.)
- (b) Mays et al. showed that radium isotopes concentrate in the melanocytes of the eye. Later it became clear that these ocular lesions appeared at lower doses of ^{226}Ra than were needed to include bone sarcoma. No such lesion has been seen in the eye of man or primates.
- (c) The nuances of this procedure are taken up in some detail in one of the quarterly reports (Taylor 1965). The general health of the colony and prolongation of life span to allow expression of the really long-term effects were paramount. Only bone changes, signs of osteogenic sarcoma, or other entities clearly associated in the past with ionizing radiation effects, were left without the best of therapy, and no animal was allowed to suffer unduly.

Dougherty and Rosenblatt summarized the long-term hematological changes for the five key elements in 1971. There was great similarity of effects among the nuclides, but some quantitative differences. They give "median hematological RBE's"^(a) for the first year postinjection using $^{226}\text{Ra} = 1$ as: $^{228}\text{Th} \approx 4$; $^{239}\text{Pu} \approx 4$; $^{228}\text{Ra} \approx 2$; and $^{90}\text{Sr} \approx 0.5$. While in the same direction as their relative effectiveness in bone, the differences are in general smaller. The extra effectiveness of plutonium and thorium is attributed to their ability to irradiate bone marrow from their deposition sites on bone surface.

Blood chemistry findings, while showing many changes, were not interpretable as more than reflecting the changing clinical status of the animals.

d. Retention and Dosimetry

The reader will note that the doses in figures 8.8.A and 8.9A,B are given in rad. This contrasts to the practice in ANL work where the dose is characteristically given as administered dose in $\mu\text{Ci/kg}$. The reason for this is partly that the Utah group was strongly influenced by the physicists and chemists in their midst who wanted to get down to physical quantities. But it is also partly due to the great care taken in measuring retention and distribution. Remember *three* measures were used.

Equations for retention and excretion began to appear with the earliest moderately complete results. Each additional group of animals and passage of time allowed elaboration and improvement of the functions. These are updated in each semiannual and annual report.

In the 1961 symposium volume, Stover, Atherton, and Mays (1962) present data for the first thousand days for ^{226}Ra , ^{228}Ra , ^{239}Pu , ^{228}Th , and ^{90}Sr showing total retention, plasma concentration as a function of time, and, of course, skeletal retention. Some of these are outlined below.

Parent Nuclide	Decay Products	Total Retention(a)	Skeletal Retention(b)
Ra^{226}		$R = 0.79t^{-0.20}$	$B \approx R$
	Rn^{222}	$R = 0.045$	$B \approx R$
Pu^{239}		$R = 0.90 - 0.0043t^{0.52}$	$B = 0.72t^{-0.04}$
Ra^{228}		$R' = 0.79t^{-0.20} e^{-\lambda t}$	$B' \approx R'$
Th^{228}		$R' = (0.19e^{-0.0011t} + 0.69)e^{-\lambda t}$	$B' \approx 0.65e^{-\lambda t}$
	Ra^{224}		$B' = 0.53e^{-\lambda t}$
	Tn^{220} and its decay products		$B' \approx 0.45e^{-\lambda t}$
Sr^{90}		$R' = 0.68t^{-0.21} e^{-\lambda t}$	$B' \approx R'$
	Y^{90}	$R' \approx 0.68t^{-0.21} e^{-\lambda t}$	$B' \approx R'$

(a) Fractional Retention ($R' = R e^{-\lambda t}$).

(b) Biological Fractional Skeletal Retention (B).

Fractional Skeletal Retention ($B' = B e^{-\lambda t}$). (b)

Biological Fractional Retention (R)

(a) The ratio of dose rates from a radionuclide that produces a 50% depression in blood cells using the dose rate from ^{226}Ra required to produce the same effect as unity.

(b) This is reproduced as in the original. It should probably be $B' = B e^{-\lambda t}$.

Thus, we see something of a mixture of the power function seen in the ANL and some other studies, including data for man with ^{226}Ra and a modified exponential. The most complex function is for the most complex element, ^{228}Th . Each of these was determined by empirical fits to the data and represents a generalization. These are translated to doses to the skeleton in the ten-year summary paper by Dougherty et al. (1962a,b).

A review of the equations and procedures was produced as a separate Utah Project report (Lloyd 1970) and in annual reports for 1977 (COO-119-252), 1978 (COO-119-253), and 1979 (COO-119-254). It is of interest to note that there was considerable variation in retention and that the dose had to be calculated for each individual dog for ^{226}Ra , ^{228}Ra , and ^{90}Sr (and in the later work also for ^{241}Am , ^{247}Cf , and ^{252}Cf). But for ^{239}Pu , ^{228}Th , and ^{224}Ra , a single composite function could be applied based on average skeletal retention equations. Much of the same material was presented in the open literature by Lloyd et al. (1976). As the total time approached fifteen years or more, the preferred representation became a series of exponentials with no power function component. This is not surprising, for as more and more points were gathered, the true nature of the relationship could be set out for functions which with fewer points looked like a power function.

Some typical retention curves with both average and individual curves can be viewed in the 1970 report and 1976 publication. The actual equations taken from the 1979 annual report are shown in table 8.7.

These equations are for either an average animal or an individual and were utilized for most of the dose calculations. Obviously they give average dose. Much work was done in the Utah group, as elsewhere, to determine the target cells (e.g., endosteal cells for bone cancer) and the probable dose to them. These efforts included quantitative autoradiography, some using alpha track counting methods (Sears, Jee, and Mays 1962; Jee et al. 1969; Taylor et al. 1969b; Jee, Dell, and Davis 1971; Smith et al. 1977); electron microscopy of the effects (Whitson and Jee 1971); careful calculation for the ranges of alpha particles and microscopically determined sites of localization (Mays 1958 and 1960; Mays and Sears 1962; Mays and Tueller 1964); and the usual analysis of macrodistributions among bones and major subdivisions of other organs.

Each of these papers, or the ideas pertinent thereto, has been presented also in the open literature, sometimes in less detail than in these project reports. They are too numerous and extensive to cite here. The anniversary volumes are listed at the end of this section. A harbinger of the depth and quality of publications to come can be seen in the paper by Jee et al. in the tenth anniversary symposium in 1961 (Jee et al. 1962). They were still at it for the twenty-fifth anniversary volume (cf, e.g., Stover 1976) and in the 1969 and 1975 IAEA symposia.

These studies and derivations are still undergoing refinement for such factors as dose rate, age effects, species differences, even strain differences. In the following section, we will review some of these and other ramifications of the Utah Project that have carried it considerably beyond the initial concept.

8. Extensions of the Utah Project

It is almost inevitable that a project as large and complex as the Utah undertaking would generate the need for more work to follow through on ideas generated en route. We can take space to review these only by a somewhat cursory listing.

TABLE 8.7. Retention Equations^(a) for Nine Elements in the Beagle as of 1979

$^{226}\text{Ra} = 0.412e^{-0.558t} + 0.105e^{-0.0730t} + 0.196e^{-0.00488t} + 0.287e^{-0.000299t}$ (5-level only)
$^{226}\text{Ra} = 0.251e^{-0.982t} + 0.211e^{-0.269t} + 0.210e^{-0.0155t} + 0.177e^{-0.00204t} + 0.151e^{-0.000150t}$ (lower levels)
$^{222}\text{Rn}/^{226}\text{Ra} = 0.075 (1 - e^{-0.181t}) t^{0.158}$ (all levels)
^{239}Pu (dose level 5) = $0.07e^{-0.0011t} + 0.43$
^{239}Pu (dose level 4) = $0.11e^{-0.0011t} + 0.39$
^{239}Pu (dose level 3) = $0.15e^{-0.0011t} + 0.34$
^{239}Pu (lower levels) = $0.29e^{-0.0011t} + 0.21$
$^{228}\text{Ra} = 0.251e^{-0.982t} + 0.211e^{-0.269t} + 0.21e^{-0.0158t} + 0.177e^{-0.00237t} + 0.151e^{-0.000479t}$ (pure at $t = 0$)
84% retention of <i>in vivo</i> produced ^{228}Th and daughters. ^(b)
$^{228}\text{Th} = 0.69e^{-0.00113t}$
$^{224}\text{Ra}/^{228}\text{Th} = 0.895$
$^{212}\text{Pb}/^{228}\text{Th} = 0.866$
$^{90}\text{Sr} = 0.36e^{-0.95t} + 0.29e^{-0.12t} + 0.10e^{-0.0092t} + 0.12e^{-0.0020t} + 0.13e^{-0.00022t}$
^{241}Am (dose level 5) = $0.359 + 0.157 (1 - e^{-0.0065t})$
^{241}Am (dose level 4) = $0.359 + 0.141 (1 - e^{-0.0029t})$
^{241}Am (dose level 3) = $0.359 + 0.076 (1 - e^{-0.0021t})$
^{241}Am (lower levels) = $0.359 + 0.015 (1 - e^{-0.0014t})$
$^{249}\text{Cf} = 0.498e^{-0.0000794t}$
$^{252}\text{Cf} = 0.498e^{-0.000791t}$
$^{224}\text{Ra} = 0.528e^{-0.214t} - 0.228e^{-9.01t}$ with the effective retention of ^{224}Ra daughters of: ^{220}Rn and $^{216}\text{Po} = 0.486e^{-0.214t} - 0.276e^{-4.65t}$ $^{212}\text{Pb} = 0.447e^{-0.214t} - 0.336e^{-2.40t}$ $^{212}\text{Bi} = ^{212}\text{Po} + ^{208}\text{Tl} = 0.391e^{-0.214t} - 0.350e^{-2.38t}$

(a) These include both radioactive decay and biological elimination. Thus, times calculated therefrom are *effective retention times*.

(b) The ^{228}Ra figures include contribution from ^{228}Th contamination in the injection solutions and are based on the newly determined half-life for ^{228}Ra of 5.77 ± 0.02 years.

Source: Reset from Utah Report COO-119-254, *Research in Radiobiology*, Annual Report, 31 March 1979, Appendix p. A-4, A-5.

- a. The need to add new dosage levels and what they were has already been described.
- b. Americium-241 was added for the reasons described in section VII. Curium-244 and -243 were added at about the same time with studies in mice reported much later (1976).
- c. Californium-249 and -252 were added considerably later for comparison with plutonium and radium. Californium-252 decays by spontaneous fission in a few percent of its disintegrations and thus has been proposed for possible neutron sources of very small size. Production in considerable quantities is anticipated (Seaborg 1973). The isotope ^{249}Cf is an alpha emitter and should have metabolic properties identical to ^{252}Cf . Thus, a direct comparison of an alpha emitter and a fission fragment was possible. Also, the discrete gamma rays of ^{249}Cf (333 and 388 keV) allowed for easy tracing of its movements in contrast to the more or less continuous gamma spectrum of ^{252}Cf . Early results were presented in a series of articles in the annual report for 1971 (Lloyd et al. 1971; Dougherty 1971; Taylor et al. 1971; Stevens and Bruenger 1971a,b; etc.). Berkelium-249 was used briefly for a soft tissue localization experiment. Discussion of results of these and many other experiments with transplutonic elements is reserved for a special section.
- d. Radium-224 was entered quite early for comparison of a short-lived radium isotope that would deliver most of its energy at the point of initial deposit, bone surface, with the much longer-lived ^{226}Ra , which soon gets buried by bone growth and turnover. This was well before discovery of the German patients and the findings reported in chapter 1. Because of the studies of German patients, a new and larger experiment with ^{224}Ra in the beagles was added. The results followed the pattern already described in chapter 1.
- e. To get a better grasp of age effects, especially with plutonium, groups of animals were added with injection occurring at three months or at five years of age in contrast to the standard seventeen-month-old animal. Results of these ramifications are still quite incomplete. Some early indications are given by Jee et al. (1975).
- f. Polymeric plutonium was substituted for the monomeric plutonium citrate to check on the role of mobilized deposits from the liver in increasing the initially very low bone deposition and on bone as compared to liver pathology.
- g. Plutonium-238 was studied for intraorgan distribution in the cynomolgus monkey (reported in 1977).
- h. The skeletal toxicity of plutonium in a group of St. Bernard dogs was tested for comparison with the beagle. The St. Bernard has a high natural incidence of bone tumors compared to the almost zero natural incidence in the beagle. There appeared to be a direct relationship between spontaneous and radiation-induced sensitivity. The latent period for tumor induction in the St. Bernard has been less than one-half that in the beagles in the results so far. Fortunately, this did not seem to foster a compulsion to make the St. Bernard the animal of choice for further work!
- i. The deer mouse and the grasshopper mouse were introduced for pilot studies as rodents that might be more suitable for long-term work than the usual laboratory strains.
- j. Because of accusations that possible genetic changes were not being properly evaluated in this huge enterprise, a special effort was made to determine again, and more precisely, the concentrations of transuranium elements in gonadal tissue (Mays, Lloyd, and Atherton 1974). There will be more

discussion of this in later chapters, even though the concentration in gonads was vanishingly small in the case of the actinides.

9. Concluding Comments—Anniversary Volumes

The Utah Project has gone far beyond its original concept and has provided toxicity information to meet all of the empirical needs. It must be remembered, however, that most of the work represents the results of a single intravenous injection. Other projects have attacked the ingestion and inhalation routes. But all have met around the insights provided into the mechanisms of handling bone-seeking radionuclides in living organisms, tissues, and cells, and a few revelations regarding some of nature's most closely guarded secrets—the mechanisms of carcinogenesis. In chapter 21 we will review a few of these.

The symposia and special publications that occurred on or around significant anniversaries in the life of the Utah Project are listed below with their published volumes. The times are approximate and have some slippage according to when one chooses to consider that the project started and when they managed to get an international group together.

Symposium	Publication
1. Second Annual Conference at University of Utah, 1954	<i>Second Annual Conference on Plutonium, Radium and Mesothorium.</i> C. N. Stover, Jr., ed. AEC Report, TID-7639.
2. Ten Years Heber, Utah, May 8-11, 1961	<i>Some Aspects of Internal Irradiation.</i> J. H. Dougherty, W. S. S. Jee, C. W. Mays, B. J. Stover, eds. Pergamon Press, New York-Oxford 1962
3. Fifteen Years Sun Valley, Idaho, September 12-14, 1967	<i>Delayed Effects of Bone-Seeking Radionuclides.</i> C. W. Mays, W. S. S. Jee, R. D. Lloyd, B. J. Stover, J. H. Dougherty, G. N. Taylor, eds. University of Utah Press, Salt Lake City, 1969
4. Twenty Years University of Utah, October 1970, Honorary Degree Ceremony for Glenn Seaborg	<i>Radiobiology of Plutonium.</i> B. J. Stover, W. S. S. Jee, eds. J. W. Press, Salt Lake City, 1972
5. Twenty-Five Years Sun Valley, Idaho, October 6-9, 1975	<i>Health Effects of Plutonium and Radium.</i> W. S. S. Jee, ed. J. W. Press, Salt Lake City, 1976.

To determine the Utah contributions, it is suggested that the names attached to the references for this section of this chapter be searched out. Remember that many of the Utah symposia, particularly in later years, embraced much more than Utah results. Indeed, as the Project matured, these meetings became prominent among the correlators, as well as the data contributors.

The "Founding Fathers," all but one (Langham), remained actively concerned with the project, and met in advisory capacities for several years. But it is clear that the undertaking conceived thirty years ago is fully mature and now with a new Director, Dr. McDonald E. Wrenn, recently of New York University, is ready to carry its ideas into still other fertile fields, provided funding continues.

C. The Davis Beagle Project

At almost the same time as the Utah Project was being organized, the School of Veterinary Medicine at what is now the University of California at Davis undertook a study of the consequences of graded and fractionated exposures to x-irradiation in the beagle. The chief objective was the study of reproductive performance. But many other measures were added.

At this time (early 1950s), Davis was the Agricultural Experiment Station or University Farm in the California system^(a) and a good site for a beagle colony. In fact, it may well be that the first proposals anywhere for use of the beagle dog in long-term king-sized experiments came from George Hart, then Dean of the Veterinary School at Davis. The origin of the idea for this project is not as clearly documented as for the Utah Project. A contract was let in January 1951 for the external radiation work. This was placed in the hands of a young veterinary protégé of Dean Hart, A. C. ("Bud") Anderson, with help from some other veterinarians (Hal Parker, John Luick) and some biometricians (L. Rosenblatt, Fred Schultz). The first step was development of a breeding colony followed by many years of operation as AEC "Project Four" for the external radiation work.

The proliferation of problems from the fallout attendant upon nuclear weapons testing made urgent the gathering of knowledge on the metabolism and effects of radionuclides after *ingestion* for long periods, i.e., an experiment more imitative of actual exposure conditions than the Utah Project. Utilizing the presence of the large and growing beagle colony at Davis seemed appropriate for an ingestion study to parallel the intravenous work at Utah.

In 1956, the AEC negotiated a contract with the school for "Project Six" in which suitable numbers of beagles were to receive ⁹⁰Sr in their daily food. The work began initially under A. C. Anderson, but later a radioisotope man, Leo Bustad from Hanford, and some other staff with background in internal emitter research, were brought in (see Appendix B).

Although we hear much less about it, there seem to have been some "Founding Fathers" for the Davis Project as there were for Utah. Indeed, some of the same people appear: Austin Brues and Wright Langham initially, followed very soon by Robley Evans and Harry Blair. H. D. Bruner of AEC Washington carried much of the organizing and planning burdens. It is reported that the early meetings of this group even utilized a court stenographer with the usual reams of unmanageable notes resulting (Goldman 1980).

The unit level (i.e., No. 1 level) of the Davis experiment was planned to be identical dosimetrically to the 1 level in the Utah Project. Work was started in a borrowed U.S. Air Force trailer. The exposures began essentially at conception and continued until the animals were 540 days of age. Thus, this experiment differed from the one at Utah, not only in utilizing the ingestion route, but in having essentially continuous intake for an appreciable period.

To tie further to the Utah project, and to the experiences in humans, a series of animals were given ²²⁶Ra. But these were given not orally or as a single injection, but in a series of eight semimonthly intravenous injections starting at 435 days of age, comparable to the time the Utah dogs (first phase) received their single injection. For further cross-referencing purposes, a smaller series of dogs received ⁹⁰Sr in a single intravenous injection at 540 days of age.

(a) It did not become an official campus of the university system until 1959.

There were morphologic studies of bone utilizing a variety of techniques: microdosimetry, cytogenetics, and forays into bone marrow culture and immunologic research. All of these were in addition to the conventional life-span, tumor-incidence, and clinical studies.

In 1973, Dr. Bustad left Davis to become Dean of the Veterinary School at Washington State University, his alma mater. Dr. Marvin Goldman, who had had in-depth experience with strontium research from the days of his doctoral thesis and other research at Rochester, took over.

Table 8.8 shows the dosage levels and general protocol of the experiment as of 1973. It did not change much thereafter. Note that the factors between the doses are comparable to those in the Utah Project.

TABLE 8.8. Davis Beagle Project: Experimental Design of Radionuclide Toxicity Studies

²²⁶ Ra Injection Series (Eight Semimonthly IV Injections Starting at 435 Days of Age)

Since the Davis work on radioisotopes was developed entirely as a result of the problems of fallout from nuclear weapons testing, details of the results belong properly in chapter 13 and will be reserved for that discussion. Our interest here is the general design of the project for comparison with the other large beagle experiments. It is interesting to note that ^{226}Ra was again the benchmark, but after multiple rather than single injections, while there was a single-injection strontium group for direct comparison with Utah. But the main thrust was ingestion over a long period, which included gestation and infancy. Thus, several new variables were added, but the "Founding Fathers" and the local staff felt they had sufficient ties into other experiments to minimize any possible variations due to strain of animal, experimental conditions, etc.

The Davis Project did not formalize its anniversaries to the same degree as the Utah group. Their contributions will be obvious in chapter 13. But they did sponsor one major symposium, which came out as a separate publication, *Biomedical Implications of Radiostrontium Exposure*, edited by Marvin Goldman and Leo Bustad and issued as one of the AEC symposium series books (Goldman and Bustad 1972).

The Davis Project has now become an integral part of the University of California, Davis, School of Veterinary Medicine, has contributed considerably to knowledge of fundamental mechanisms, as well as the initial programmatic goal, and is now undertaking work related to a variety of nonnuclear energy sources. Its staff and students are also an integral part of the teaching program of the school.

Perhaps because of the initial orientation of the campus and its strong ties to the veterinary school, the work at Davis has produced a number of important papers on general aspects of the development of large animal colonies for research and that often neglected, but vitally important topic, the role of the animal caretaker in the success of such undertakings. Beside the truism "Blessed is the researcher or administrator who has a fine secretary" should go, for those involved in any long-term animal study, "Blessed is he (or she) who has an intelligent and dedicated animal care establishment." Agricultural communities are more likely to be so blessed.

D. The Lovelace Project

The last of the de novo king-sized experimental installations for internal emitter toxicology was developed at what was then known as the Lovelace Foundation for Medical Education and Research in Albuquerque, New Mexico. Work on the inhalation of elements that emit alpha particles, such as plutonium, polonium, uranium, and radon and its decay products, was under way at Hanford and Rochester as we will review in the chapter on inhalation toxicology. But despite the importance of the inhalation route, relatively little work was being done on the long-term effects of inhaled fission products. This was not surprising, for very special facilities were required to handle aerosols of these beta- and beta-gamma-emitting elements.

Largely at the instigation of H. D. Bruner at AEC Headquarters, and with important assistance from Dr. C. W. Shilling, deputy director of the Division of Biology and Medicine, it was decided to develop yet another large project centering on beagles to get the much needed information on fission products. Because of possible radioactivity hazards, an isolated site was desirable. Hanford had the isolated sites, but was already working at capacity. Rochester was far

from isolated and not a good site for such a program. The Lovelace Foundation, itself located close to the edge of the desert in Albuquerque, had been conducting extensive work for the Air Force on blast biology and had use of an area of the Sandia Base a few miles from the clinic. The blast biology work was winding down, and W. Randolph Lovelace, Jr., son of the founder of the clinic, evinced interest in some new work. After the usual meetings and probings, a decision was made to build and staff a facility then called the "Fission Product Inhalation Studies" in the desert not far from the earlier facility. While the clinic staff was oriented primarily to clinical medicine, there was much talent available in the area for consultation and help in developing staff, since both the Kirtland and Sandia bases were closely associated with the weapons programs.

Lovelace (Randy) placed C. S. (Sam) White, who had headed the blast biology work, in charge of developing the facilities and gathering a staff. A purebred beagle colony was established in 1961 using dogs from some of the other large AEC projects and also commercial breeders. The details of development and the care and breeding of this colony have been given by Redman et al. (1970).

A unique facility was created, which, among other things, utilized the abundant evaporative potential of the desert climate to greatly reduce the volume of liquid waste requiring disposal by the use of open holding ponds. Good separation of "hot" and "cold" operations was facilitated by the abundance of land to spread out upon.

In due course, the staff was assembled, many of them trained at Rochester in aerosol physics and inhalation toxicology and pathology. There were no formal "Founding Fathers," but there was considerable exchange with other laboratories doing inhalation work, accomplished through the AEC Headquarters staff, particularly Dr. William Lotz who had assumed some of the administrative work for the internal emitter research with H. D. Bruner. A group called the "Inhalation Toxicology Working Group" met rather frequently at the cognizant laboratories. Some meetings of this group placed special emphasis on the plans for the Lovelace experiments.

With the death of Randy Lovelace, Sam White had to assume broader responsibilities, and a full-time director was needed for the inhalation program. Fortunately, Dr. Roger O. McClellan, a veterinarian who had had experience for many years at Hanford, and also a tour of duty at AEC Headquarters, was persuaded to go to Albuquerque in 1966, and the laboratory has grown, diversified, and prospered ever since.

In the early 1970s, the several parts of the Lovelace organization were consolidated as the "Lovelace Medical Foundation." The inhalation research became a subsidiary corporation of the Foundation, the Inhalation Toxicology Research Institute (ITRI), to recognize that its interests and work had gone into areas beyond the original fission product research. And finally, as the general program broadened still more to include environmental contamination problems with both radioactive and chemically toxic pollutants, the parent organization became The Lovelace Biomedical and Environmental Research Institute.

The work was not confined to the dog, especially for aerosol and short-term toxicity studies. We will review it in chapter 9.

The primary thrust of the results pertain, of course, to the inhalation route of exposure and its special problems. Thus, discussion of the findings and their relation to other inhalation toxicology programs will be reserved for chapter 9. Key personnel in the organization will be found in the publications listed in that chapter and also, briefly, in Appendix B.

IV. Almost New Projects: Hanford and Los Alamos

In chapter 7, we had only a glimpse of the wartime work at Hanford because it was largely monitoring plus a rather extensive environmental program, which we will review in chapter 11. We also looked very briefly at the immediate postwar aspects that were tied directly to the World-War-II operations. In essence, both of these activities were centered on personnel or environmental monitoring, except for the important bio-effects program at Hanford in aquatic biology.

Very soon after the organization of the AEC, i.e., in 1947, both Hanford and Los Alamos expanded greatly in the field of biomedical research, as contrasted to monitoring and worker protection. Since these expansions were built upon an existing core of personnel and ideas, they cannot be regarded as "new" projects in the sense that Utah, Davis, and Lovelace were established *de novo*. But they were different enough from the wartime effort to be regarded as "almost new." Both Hanford and Los Alamos have contributed enormously to fission product and actinide studies, as well as in other areas, throughout the 1950s, 1960s, and 1970s. We will review briefly their growth and contributions in turn in the next two sections of this chapter.

A. The Hanford Biology Operations^(a)

1. Immediate Postwar Developments

In the late 1940s, Herbert M. Parker, who headed the Health Instruments (HI) Division of the Hanford Works throughout the war years, initiated expansion into a practical program in radiobiology linked to the hazards to humans and the environment that had arisen in their work. Karl Herde and Dick Foster had been in the environmental work for many years, but as a division separate from HI. In fall 1946, these operations were consolidated as a biology section under the Radiological Sciences Division, which Parker headed. In 1947, Harry Kornberg came aboard to head a biochemistry section, and before long he became manager of the entire biology operation. P. L. Hackett, L. K. Bustad, R. F. Palmer, S. Marks and other names we associate with long tenure at Hanford appear in the first annual report covering the year 1951.

Facilities were made available rather quickly by renovation of a sizeable building near one of the production reactors. This was "onsite," which at Hanford meant about thirty miles from the town of Richland. There was ample space for construction of satellite facilities for holding and care of large animals. Its isolation made the possible contamination of inhabited spaces much less of a worry than had it been close to town or on a university campus. But it also meant an onerous trip for personnel needing to observe or care for animals at odd hours.

2. Iodine and Sheep

One of the first major experiments concerned ¹³¹I. During the war years, environmental surveys around the reactors had shown its presence, and monitored rabbit thyroid glands had confirmed significant, though not dangerous, concentrations therein. Iodine appeared to be more prevalent in the reactor off-gases

(a) Later Pacific Northwest Laboratory (PNL), operated by Battelle Memorial Institute.

than most of the other fission products. Leo Bustad, a competent veterinarian and researcher, spearheaded the iodine work. They chose sheep rather than dogs as the experimental subject, perhaps because the real problems at sites like Hanford, indeed most reactor sites as then known, could easily involve large herds of grazing animals. Also, the limiting hazard was deposition on vegetation and intake by grazing animals rather than direct inhalation.

The first Hanford annual report in biology (Report HW-25021, 1952) gives a general description of a low-level chronic-effects experiment, histopathology of the thyroid gland and the changes in blood constituents (i.e., clinical chemistry). Reports on this iodine experiment with sheep appear in every annual report up to 1961, and occasionally thereafter. The bulk of the work involved feeding the contaminant to the sheep to tie as closely as possible to problems in the field. The results are nicely summarized in a special paper published in *Radiation Research* (Bustad et al. 1957) and along with work from other laboratories in the Hanford biology symposium held in June, 1963, and published in *Health Physics* (Bustad 1963).

This project was not only the first long-term experiment with iodine in a large animal, but probably the first project to get under way involving multigeneration, chronic administration of a radioisotope to a large animal. It was started in April 1950 with ewes in an advanced stage of pregnancy. The iodine was added to the feed in the form of drilled pellets and administered daily. Selected offspring were placed after weaning on the same regimen, and most groups continued for at least three generations.

The levels administered in both the initial and subsequent phases are summarized in table 8.9. The lowest level (0.005 $\mu\text{Ci/day}$) was calculated to deliver a dose rate to the thyroid, after uptake of 0.3 rad/wk, equal to the maximum permissible exposure to whole-body penetrating radiation in humans. The other levels were chosen arbitrarily to cover a considerable range in order to establish the thyroid ablative dose.

The 1,800- and 240- $\mu\text{Ci/day}$ levels were found to produce complete destruction of the gland and were discontinued after 420 and 450 days, respectively. The lowest level, 0.005 $\mu\text{Ci/day}$, was discontinued when it became clear that even the 0.15- $\mu\text{Ci/day}$ level was apparently without observable effect. Intermediate levels of 135, 45, and 15 $\mu\text{Ci/day}$ were inserted to get more information in the region between ablation and no effect.

A flowchart for the experiment is reproduced as figure 8.11 taken from Bustad et al. (1957). The results appeared not only in the special summaries already cited but also in the annual reports over a number of years. They were not conspicuous in the routine literature, being better suited to larger compendia. The results are described briefly below:

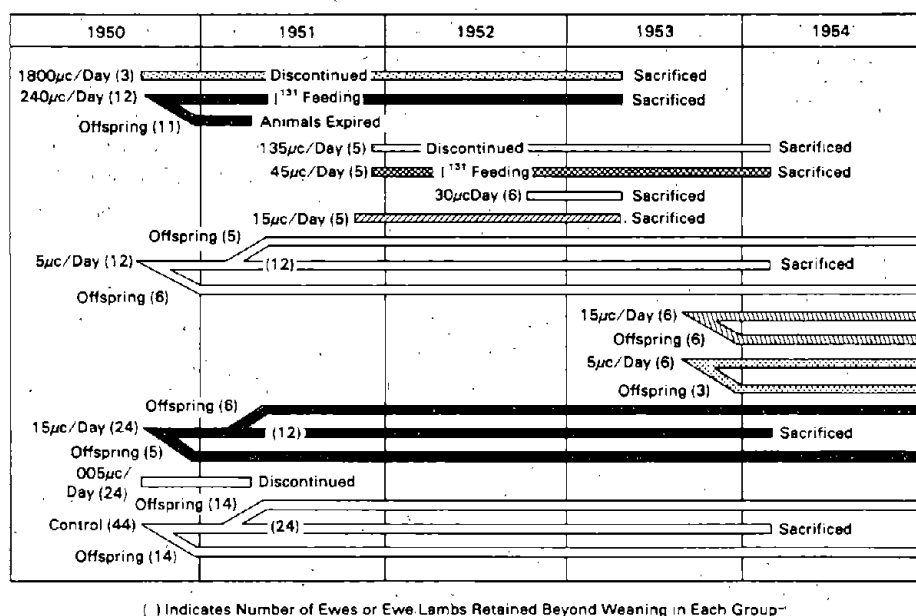

FIGURE 8.11. Experimental design for Hanford experiment with ¹³¹I in sheep. (Redrawn from Bustad et al. 1957. Reprinted with permission of Academic Press, Inc., Orlando, Florida, copyright 1957.)

1. Thyroid activity was diminished in all ewes fed 5 μ Ci, or more, per day. External monitoring showed this well ahead of the development of clinical symptoms.
2. Specific damage was caused by ¹³¹I in structures close to the thyroid, and there was ulceration of the mouth and lymphopenia. Otherwise the effects of ablative doses produced changes similar to surgical ablation of the thyroid.
3. Systemic clinical manifestations were, in general, those of thyroid deficiency.
4. Conception and breeding seemed normal in the first generation, but ewes in the second generation failed to produce live offspring at the two highest levels. Reproductive performance was surprisingly good at the lower levels, even in the presence of some thyroid damage.
5. Uptake of ¹³¹I by the thyroid was fairly avid in the low-dose groups because the basic diet was marginally goitrogenic (by design). It was highly variable in the treatment groups because of significant damage. Uptake of ¹³¹I fed daily was one of the most sensitive indications of thyroid damage.
6. No thyroid damage was observed in animals receiving 0.15 μ Ci/day (equivalent to a thyroid dose of about 3 rad/wk).

7. One metastasizing fibrosarcoma developed in or immediately adjacent to the thyroid of one ewe that had received $5 \mu\text{Ci}/\text{day}$ since weaning and whose dam had received the same dose during the latter third of the gestation period and all of the lactation period. This was at a level about thirty times the "indifference" level.

The estimated thyroid doses at levels associated with damage are considerably higher than in many other dose-response situations. For example, at $5 \mu\text{Ci}/\text{day}$, where thyroid damage ranged from none to moderate, the calculated doses ranged from 18,000 to 40,000 rad in the thirty-five to fifty-two months of exposure. Even with the uncertainty about what the true weight of the gland was, the levels are all quite high. Ablation doses were over 100,000 rad (with some doubt in the calculation as to how much of the calculated dose was really needed).

Later extensions of the experiments included single intravenous doses, multiple but widely spaced doses, double tracer experiments using ^{125}I and ^{131}I , and a formal comparison of the effect of route of administration. (The difference was less than the variation of uptake between individuals.) Many other aspects were developed, but these fit more conveniently into the problems of fallout and will be discussed in chapter 13. An illustration of the effects on growth is given in figure 8.12.

FIGURE 8.12. Variable growth retardation in three nine-month-old lambs fed $240 \mu\text{Ci}/\text{day}$ with a control animal (on left) of same age. (From Bustad et al. 1957. Reprinted with permission of Academic Press, Inc., Orlando, Florida, copyright 1957.)

3. Miniature Swine

The sheep as a ruminant was not a very good physiological model for extrapolation to humans. Bustad and his colleagues turned to swine for some final iodine work and especially for the new studies with radiostrontium. The pig is an omnivore with dietary requirements and gastrointestinal tract similar to man's. Some early experimental work was actually done at Hanford with the standard porker. But the difficulties and hazards of doing daily experimental work with these enormous and ill-tempered beasts led quickly to the use of miniature swine. First they used Hormel miniature swine, then the Pitman-Moore strain, and for most of the long-term work a cross between the Pitman-Moore and large swine. These have frequently been referred to as "Hanford miniature swine." In addition to the greater ease of handling over the full-sized porker, the miniature swine have a mature weight and organ weights quite comparable to those of man, as well as the similarities in diet and gastrointestinal tract characteristics mentioned earlier. Also, they have a white skin, very useful for studies with topically applied sources.

Some of the characteristics of miniature swine are described by Horstman et al. (1960) and in a symposium (Bustad and McClellan 1966). A special metabolism cage for collection and separation of excreta from these miniature pigs is described in the 1956 annual report (Report HW-47500, 1957). Figure 8.13 is a photograph of a standard porker and the "Hanford miniature swine."

FIGURE 8.13. Comparison of Hanford miniature swine (right) with standard porker. (Courtesy of Pacific Northwest Laboratory.)

Just as the sheep was the anchor species for the iodine work, the miniature swine became the standard large animal at Hanford for major studies with radiostrontium (results described in chapter 13), and for occasional trials with other radioisotopes. The first beagles arrived at Hanford in 1956 for subsequent extensive inhalation studies with plutonium and other transuranics, and the uranium daughter products of importance in uranium mining (chapters 3, 9).

4. Tritium

At almost the same time as the iodine work was started, Roy Thompson, who came to Hanford in 1950, began major studies with tritium. This was also related to Hanford's wartime experiences. Tritium was produced in the reactors as both a fission product and as a result of neutron activation. Also, potentially large releases could occur in the fuel processing operations. The rather considerable production of tritium in the fusion process tied the work nominally to the thermonuclear weapon developments, and the presence onsite of some large sources of tritium, for this project, made the connection much more than nominal. The reports of these experiments appeared in the first annual report (1951) and continued each year until 1955. Early published papers concerned primarily metabolic turnover of tritium as a tracer in rodents (Thompson 1952, 1953, and 1971; and Thompson and Ballou 1954). All of this work showed rapid and complete absorption from the gastrointestinal tract and rapid passage into organs, tissues, and various body fluids. Also, combination with organic moieties was described, and the importance of the ratio between organically bound tritium and free-water tritium to retention times and modes of distribution was pointed out. As Totter remarked at the dedication of the new Life Sciences Laboratory at Richland in 1971, this work (along with studies on man at Los Alamos) constituted some of the earliest definitive experiments on the radiation biology of tritium in mammals.

Small animals were used for most of this work. Elimination by rats and mice showed three half-times, as given by Woodard (1970) from the Hanford and other work as three, ten, and seventy days. These were consistent with the half-times of about eight, twenty, and four hundred days described in man, the slower rate being due to the slower turnover of body constituents in man.

This work, confirmed by a growing crescendo of all types of work with tritium and tritiated water, led to consideration of tritium as one of the least hazardous of the radioactive isotopes. Its low energy poses no danger from external exposure and a very short range for internal exposure. The rapid loss and dilution in body water reinforced this conclusion. But even the early Hanford work indicated that a small amount of tritium acquired as water is incorporated into tissue compounds with retention half-times up to one-third of the life span. Here began a long saga of the importance, or lack of it, of tritium incorporated into key cell constituents—which we shall review in later chapters along with inhalation studies.

5. Radioactive Particles

The "radioactive particle" work was again the result of a local phenomenon—accidental releases, albeit short, of radioruthenium in particulate form from the production plant stacks. There was much concern that these particles, if in the respirable-size range, might act as focal points for lung cancer or, if introduced by other routes, might cause injury out of proportion to the amount of

radioactivity involved. This was one of the origins of the "hot speck" or "hot spot" problem—similar to, but not to be confused with, the hot spot problem in bone. Reports on research with radioactive particles first appear in Hanford annual and other reports in the early 1950s.

6. Plutonium (Except Inhalation)

It is no surprise that biological work with plutonium and other actinides developed in the Biology Department at Hanford. But because of the extensive war work at the Metallurgical Laboratory, at Berkeley, and at Rochester, there was not the pent-up demand for urgently needed data connected with the daily operations of the plant as seen in the case of some of the other work. Reports on plutonium appear in the first annual report. These early reports concerned absorption of plutonium from the gastrointestinal tract and skin as well as treatment for internal plutonium contamination. In addition to the early work pertinent to wound contamination, there was a major effort on the therapeutic removal of these elements, one of the largest and most consistent of the several under way. The work included also gastrointestinal tract absorption, isotopic and chemical differences, behavior and effects in the young and developing animal, and the usual metabolism and effects observations under the various conditions imposed. This work extended to actinides other than plutonium, such as neptunium, americium, californium, and einsteinium, but we will discuss these separately from plutonium.

Of special interest is the rather considerable difference in metabolism of the short-lived isotopes of plutonium compared to the long-lived ^{239}Pu . For example, the shorter-lived ^{238}Pu has a shorter retention time and seems to be more mobile in general. This is quite beyond the difference in radiological half-life and has been attributed, in part, to instability of ^{238}Pu complexes possibly caused by the much greater radiolysis in tissue fluids and in part to the differences in mass.

These phenomena were extended in a study of ^{237}Pu versus ^{239}Pu nitrates in beagle dogs by Bair et al. (1974). Here the specific activity difference is from only about 80 $\mu\text{g}/\mu\text{Ci}$ for the 237 isotope to 16 $\mu\text{g}/\mu\text{Ci}$ for the 239 form. Much more ^{237}Pu was excreted in both urine and feces, much more went to skeleton and much less to liver. These differences are consistent with the idea that much more of the 237 isotope is in the monomeric form, while much more of the heavier form is in polymeric form (i.e., a radiocolloid). The difference lasted over at least thirty days and is, thus, far from a transient phenomenon.

Another example of the Hanford nonrespiratory studies is work on the combined toxic effects of plutonium plus x ray (Ballou, George, and Thompson 1962). The x rays did not change distribution or excretion of the plutonium, but the lethal effect of either x ray or plutonium is markedly increased in rats by their combined application.

It was logical to include plutonium in the work with swine. This was done by Leo Bustad and colleagues with the first published paper appearing in the proceedings of the first Hanford biology symposium held in May 1962. Naturally the work extended back over ten to a dozen years. The 1962 report (Bustad et al. 1962) gives the major objectives of the study as metabolism by various routes of administration, toxicity of plutonium compared to some other bone seekers in the pig, effects on skin and removal therefrom of plutonium injected or topically applied. (Again the motivation was from the practical problems of plutonium in wounds.) The routes of entry were intravenous, intragastric, and

intratracheal. The element was given as the valence IV nitrate. Liver contained more plutonium than bone by all routes and at all times from as short as 11 days to as long as 695 days. But the concentration ratio was much higher after intravenous than after intratracheal or intragastric administration. The fraction of administered dose reaching these organs was, of course, much lower after entry via lung or gut. This behavior is quite comparable to that seen in other species and is consistent with the idea that the intravenous route evidences much more radiocolloid formation than when the element is absorbed through gut or lung wall. The effects work reported was very preliminary but included reporting of a 40% reduction in blood neutrophil count after one-half to one year at $1.3 \mu\text{Ci } ^{239}\text{Pu/kg}$ body weight given by vein. There were also early changes in bone. There is no mention of tumor development.

A companion study by Clarke (1962) takes up the histopathology in bone in more detail and provides one of the few comparisons of plutonium with strontium and radium in the pig. Injections were made at one, five, six, or twelve months of age. There were differences in details of the damage produced consistent with the deposition of plutonium as a surface seeker and strontium and radium as volume seekers. Plutonium was consistently more damaging than ^{90}Sr or ^{226}Ra , but since the results were not amenable to quantitation, no toxicity ratio calculations were attempted. The effects in pig bone were, in general, quite comparable to those seen in the Utah intravenous studies with beagle dogs, except that the experiment did not reveal bone tumor development.

The intradermally injected plutonium was reported upon by Cable et al. (1962). There was appreciable, but not large, absorption from the injection site, with about 12% of the injected dose appearing in regional lymph nodes; about 7% in liver, and about 5% in bone. (The plutonium was injected as the nitrate.) Ulcers formed at the injection site at the highest dose, $5 \mu\text{Ci}$ of ^{239}Pu , but histopathological analysis showed changes in skin structures at lower concentrations.

This symposium saw also many reports on the other actinide elements, americium, neptunium, and californium, some of them from the Hanford group. These will be taken up as part of the general review of the transplutonic elements in section VI of this chapter.

7. Gastrointestinal Tract

The Hanford operation housed what is probably the most intensive attack in U.S. work on both radiation injury to the gastrointestinal tract and the absorption of a large number of radionuclides from the gastrointestinal tract.

It started with the early studies of Katz, Kornberg, and Parker (1955) on the absorption of plutonium from the gastrointestinal tract of rats and extension of the work to swine by Weeks et al. (1956). They confirmed in an animal with a gastrointestinal tract more closely resembling man than the rodents used earlier that normally plutonium is very poorly absorbed.

When Maurice F. Sullivan arrived at Hanford in 1955, studies began that are still being continued. In the earlier phases, the group was interested primarily in radiation injury from both external radiation sources and from radioisotopes passing through the gastrointestinal tract, the latter, in part, a result of the radioactive particle problem mentioned earlier. Much of this work, along with contemporary studies elsewhere, was contained in the sixth Hanford biology symposium (Sullivan 1968). This emphasized effects and reflected the general interest in the gastrointestinal tract syndrome then current.

As interest focused more on low levels of radiation exposure, the possible effects of small amounts of radioisotopes passing through the tract and their metabolic behavior became dominant in the work. The latter grew to be paramount as it became apparent that effects at low levels were not going to be detectable in the gastrointestinal tract. This was stimulated by the need for good figures on gastrointestinal tract absorption for the setting of intake limits for the over two hundred radioisotopes in the 1959 ICRP-NCRP recommendations for maximum permissible concentrations. Also, the fact that the gastrointestinal tract came up as a critical organ in a surprising number of cases helped to change the focus of interest.

One of the very early findings of significance, the poor absorption of plutonium in the +4 valence state from the gut, seen in Hamilton's work with the rat, was amply confirmed, as was the tendency for plutonium entering in other valence states to be converted to the +4 state. The greater absorption of ^{238}Pu and of several of the transplutonics was also made clear. Recently (Sullivan 1980), absorption of ^{228}Th , ^{232}U , ^{237}P , ^{237}Pu , ^{238}Pu , ^{239}Pu , ^{241}Pu , ^{241}Am , ^{244}Cm , ^{252}Cf , and ^{253}Es from the gastrointestinal tract was measured in neonatal rats, guinea pigs, and swine receiving the nuclides in solution or suspension by gavage. While particle size, valence state, chemical form, and age of the animal all had their effect, the absorption by newborn was uniformly twenty (swine) to one hundred (rats) times that seen in the adult. Such findings have been quite general and are not limited to the actinides. They have led to the introduction of special considerations for oral intakes by the very young.

Two basic problems have come into focus around this work at Hanford and contemporary work elsewhere. The first concerns the validity of the gavage technique for administering radioisotopes, or indeed any substance, for measurement of gastrointestinal tract uptake. The practice has been to starve the animal prior to administration to avoid combination of the radioelement with the contents of the gastrointestinal tract. This was true in the earlier Hanford work. In fact, the animals were frequently starved for a period *after* gavage for the same reason. Sullivan (1979) emphasized the fact that, when given by gavage to a starved animal, hexavalent plutonium is absorbed to almost one thousand times the extent of tetravalent plutonium. But if food is present in the gut, the hexavalent state is very short-lived, and conversion to the +4 state occurs rapidly, and absorption is considerably reduced. Thus, in his view, the higher absorption figure of the +6 state is of no practical significance in normal exposures where there is almost sure to be some food in the gastrointestinal tract. (a) These findings do not seem to apply to all elements, probably because of differences in their chemical behavior within the milieu of the gastrointestinal tract.

As a result of findings such as these at Hanford, there is now a strong tendency to administer isotopes for determining gastrointestinal tract uptake to recipients in as near a normal nutritive state as possible. The large sheep and swine experiments used this mode even in the early days, as did the beagle project at Davis. But there is much yet to learn about how much difference the presence of food makes. It seems to be isotope-specific and a subject for still further research by groups like the one at Hanford.

(a) Experiments at other laboratories, e.g., Rochester, put the animal back on regular feed immediately after gavage. It is not proven how much, if any, effect this may have on the derived figure for absorption. But this difference in practice might account for some of the variability of results seen in the literature.

The second problem of the gavage technique is the concentration of isotope and its availability rate. In the original type of gavage experiment, a considerable slug of material arrived all at one time. Some of the work using feeding techniques indicates that fractional absorption may be greater when the concentrations are low. This again appears to be true of some elements and not of others.

The Hanford people approached another facet of these problems, in part, by using different isotopes of plutonium, which because of their wide range of half-lives covered a considerable range of specific activities. Here the total mass associated with a given activity could be varied significantly. Other things being equal, the activity entering the body from a small mass was more mobile in most respects, including gastrointestinal tract absorption.

Another facet under current study provides reasons to suspect that passage through the food chain may render some elements more transportable in general, so that gastrointestinal tract absorption is higher than from a freshly mixed solution or a freshly prepared pellet of feed. A typical example of the Hanford approach to this phenomenon is seen in a paper by Sullivan et al. (1980) in which rats and guinea pigs were given alfalfa containing ^{239}Pu . Differences in absorption of up to a factor of five occurred when the plutonium was mixed with alfalfa leaves and up to a factor of ten when the plutonium was accumulated by alfalfa leaves by growth in contaminated soil. We will return to these problems when we consider environmental pathways in chapter 15.

8. Studies with the Fetal and Juvenile Mammal

We frequently hear complaints that not enough is known about the effect of age, particularly very young ages, on the behavior and effects of radioisotopes entering the body. This becomes, of course, of particular importance as the process of standard-setting shifts from occupational to population exposures. The complaint is true to a degree, but it rests more on the complexity of the problem than on simple lack of pertinent research. The Hanford group has been a major contributor to the storehouse of information we do have. While some of the studies occurred relatively early, the development of a consistent and concentrated attack dates from the arrival of Melvin Sikov at Hanford in 1965. Sikov became interested in the general problems of the effect of toxic agents, particularly radiation and radioisotopes, early in his research career (Sikov 1979). He has stayed close to the field ever since with his colleague of many years, D. D. Mahlum.

The effect of age on sensitivity to, and effects from, external radiation sources has been well established. With internally deposited radioisotopes, the problems are much more complex. Age influences absorption and distribution. As the organism grows, the size and weight of the organs change so the concentration of nuclide changes, even if the actual amount present remains relatively constant. Each element has its individual pattern, indeed different chemical forms of the same element have their individual behavior.

An informative illustration of these phenomena is found in a paper by Mahlum and Sikov (1974). The abstract of this paper tells the story and is reproduced below:

Newborn (0-24 hr. old), weanling (21 days old), and adult (4 mo. old) rats were injected intravenously with doses of monomeric or polymeric ^{239}Pu over the range of 6-90 $\mu\text{Ci/kg}$. Some animals from each age-dose-form group were killed at intervals for determination of distribution and retention while the remaining rats were

held for observation of acute mortality and several measures of delayed change. The most notable difference in partition involved a failure of the newborns to differentiate between the two physicochemical forms and an increased skeletal deposition in the weanlings exposed to monomer. As a result of these differences in deposition, as well as differences in retention and dilution, the cumulative radiation doses differed for the three ages. On an injected dose basis, monomeric ^{239}Pu was more acutely toxic to newborn rats, $\text{LD}_{50/30} = 63 \mu\text{Ci/kg}$, than to adult or weanling rats, $\text{LD}_{50/30} = 90 \mu\text{Ci/kg}$. Polymeric ^{239}Pu was more acutely toxic to adult and weanling rats, $\text{LD}_{50/30} = 47 \mu\text{Ci/kg}$, than to newborn rats, $\text{LD}_{50/30} = 77 \mu\text{Ci/kg}$. Delayed deaths, between 90 and 270 days after injection, were more frequent among adults injected with monomeric ^{239}Pu at levels of 6-90 $\mu\text{Ci/kg}$ (14/41, 90-day survivors) or among either weanling or newborn rats given either form of ^{239}Pu . Delayed effects such as mortality and mammary tumor incidence appeared to be influenced by the pattern of radiation doses associated with the physicochemical form administered and the age at exposure. (Mahlum and Sikov 1974)

A succinct summary is given by Sikov and Mahlum (1972) in which influences of age on absorption, partition, critical organ, and radiation sensitivity and the role of differential organ growth are each taken up.

Probably the earliest comprehensive study, from Hanford, of the absorption of plutonium relative to age is the one by Ballou (1958).

We can trace back the evolution of this facet of the work at Hanford by following it in the annual biology research reports.

In the report for 1961 (HW-72500, January 1962), we find:

Effect of Age on Retention of Strontium and Calcium. R. O. McClellan, A. C. Case, and H. W. Casey.

By the 1966 report (BNWL-480, July 1967), we find:

Effect of Age on Absorption of Plutonium from the Gastrointestinal Tract of Rats. D. D. Mahlum and M. R. Sikov.

Cross-Placental Passage of Actinides in the Rat. M. R. Sikov and D. D. Mahlum.

Neptunium-Induced Fatty Livers in Rats: Electron Microscopic and Biochemical Studies. J. D. Berlin and D. D. Mahlum.

Distribution of Cerium-144 in the Fetal and Newborn Rat. D. D. Mahlum and M. R. Sikov.

Age-Related Differences in the Metabolism of Cesium-137 by the Rat. D. D. Mahlum and M. R. Sikov.

Interrelationships Between Environmental Temperature and Diet in the Distribution and Retention of Cesium-137 in the Rat. D. D. Mahlum and M. R. Sikov.

Age Dependence of Radioiodine Metabolism and Effect in Rats. M. R. Sikov.

By the time of the 1971 report (BNWL-1650, Pt. 1, September 1972), a whole section is set aside and labeled as below:

Metabolism and Effects of Radionuclides in the Developing Fetus and the Young

The Carcinogenicity of ^{131}I Relative to Age at Exposure. M. R. Sikov, D. D. Mahlum, and W. J. Clarke.

Influence of Age on the Late Effects of Monomeric ^{239}Pu in the Rat. D. D. Mahlum and M. R. Sikov.

Plutonium and the Liver of the Immature Rat. M. Kashima, D. D. Mahlum, and M. R. Sikov.

Distribution and Subacute Toxicity of ^{253}Es in Weanling and Adult Rats. D. D. Mahlum, M. R. Sikov, and M. Kashima.

Distribution of ^{253}Es in the Fetoplacental Unit of the Rat. M. R. Sikov and D. D. Mahlum.

^{253}Es and ^{249}Bk Distribution in Rat Tissues Following Intragastric and Intravenous Administration. F. P. Hungate and D. W. Baxter.

The report for 1973 (BNWL-1850, Pt. 1, August 1974) carries the following pertinent papers:

Plutonium Metabolism in the Lactating Rat. D. D. Mahlum and M. R. Sikov.

Plutonium Metabolism in Immature Swine. B. J. McClanahan, H. A. Ragan, and D. D. Mahlum.

Cross Placental Studies with ^{238}Pu . M. R. Sikov, M. Dedrick, and D. D. Mahlum.

Effects on the Rat Embryo of Combined Exposure to ^{239}Pu and Trypan Blue. M. R. Sikov and D. D. Mahlum.

Effects of ^{253}Es in Weanling and Adult Rats. D. D. Mahlum, M. R. Sikov, and F. P. Hungate.

For 1974 (BNWL-1950, Pt. 1, March 1975), the material is again gathered together under a common heading:

Toxicology of Radionuclides in the Fetal and Juvenile Mammal

Influence of Age on the Development of Bone Tumors in Rats Injected with ^{239}Pu Citrate. D. D. Mahlum and M. R. Sikov.

Metabolism of ^{241}Am Citrate in Rats Relative to Age. D. D. Mahlum and M. R. Sikov.

The Toxicity and Distribution of ^{241}Am and ^{244}Cm in the Rat After Administration at Nine Days of Gestation. M. R. Sikov and D. D. Mahlum.

Effects of ^{253}Es Injected in Weanling and Adult Rats. D. D. Mahlum, M. R. Sikov, and F. P. Hungate.

Effect of Irradiation on the Development of Fetal Rat Lung in Organ Culture and in Utero. J. C. Vogt, M. R. Sikov, and D. D. Mahlum.

These listings should be enough to give both the extent and the depth of the effort concerning fetal and juvenile animals.

A Hanford biology symposium (Sikov and Mahlum 1969) brought together an international group interested in both radionuclides and external radiation effects. The published proceedings provided, in a single volume, a quite complete summary of the status of the world's literature at that time, and several papers were derived from the work reported earlier in the annual progress reports.

The greater radiosensitivity of growing tissues and organs and the key periods of special sensitivity during embryogenesis seen with external radiation sources were confirmed in the radionuclide work, but the complexities of isotope metabolism and dosimetry make generalizations difficult. In general, the work showed more rapid adsorption and greater mobility for the radioelements in very young and embryonic animals and critical dependence of effects on the stage of development. Also, in general, the differences as compared to the adult began to decrease at the time of weaning.

9. Therapy

In the discussion of radium and polonium, we reviewed some of the attempts to influence deposition or hasten removal by changes in diet or the use of various specific therapies. As we shall see in the consideration of research stimulated by the problems of fallout from weapons testing, similar ideas were applied to the fission products, especially radiostrontium.

As Thompson (1956) remarked, Hanford was a very likely place for interest in the therapeutic removal of plutonium. The possibilities of worker contamination were always nearby, and both the research and medical operations felt the immediacy of being prepared with possible therapy. Indeed, in his paper, Thompson gives a tabulation of one hundred plutonium deposition cases over a ten-year period, albeit only one thought to be above the maximum permissible level, and only three above 20% of same.

W. D. ("Dag") Norwood, the quietly competent physician who had had as his responsibility the health of thousands of construction workers who had built Hanford, and later all of the local General Electric employees, reviewed at the same Argonne conference (Norwood 1956) some of the clinical considerations surrounding therapeutic removal of elements like plutonium. Both Thompson and Norwood discuss and compare the efficacy of one of the quite early agents, zirconium citrate (whose saga we shall review in a general consideration of therapeutic measures), with one of the moderately early chelating agents, Ca-EDTA (see chapter 19). Thompson cites two papers (Katz, Kornberg, and Parker 1955; Weeks et al. 1956) and reports from the *Hanford Annual Report* for 1953. Thus, there was significant early interest and activity at Hanford relating to the therapeutic removal of deposited radionuclides. Considerable interest had persisted at Chicago and Berkeley and had grown at Los Alamos. Also, the new laboratories at Utah and Lovelace Foundation joined the effort. The big question, as we shall see later, was toxicity of the therapeutic agent.

At Hanford, one of the more sustained efforts in chelation therapy began when Dr. Victor Smith, a chemist who had come to Hanford in 1954 and worked on the ruthenium particle and plutonium inhalation exposures for a couple of years, transferred to Roy Thompson's section and became intrigued with chelation chemistry. Although many coauthors came and went, Smith could be depended upon for items pertinent to therapeutic removal in the annual reports and journal publications. This was still going on at the end of the period covered by this book. Examples are Ballou et al. (1977); Sikov, Smith, and Mahlum (1975); and sections in the annual reports for 1976 and 1977.

Discussion of the results will be held for the general review of therapy in chapter 19, except to remark on a few items of special pertinence to the Hanford setting (Smith 1979). Along with Chicago and Los Alamos workers, and studies abroad, they found the chelating agent DTPA much superior to EDTA in

removing injected plutonium citrate in rats. Norwood gave it very early trials in man in a dose of 1 g (because that was the size ampule it was packaged in).

Later, to avoid the clumsy intravenous drip administration, DTPA was placed in a small nebulizer so that it could be inhaled. Besides greater convenience, this might be especially effective for an inhalation exposure. But some questions were raised when animals receiving up to ten times the likely human dose of these aerosols showed what was termed a "transient emphysema" (Ballou via Smith 1979). Further Hanford work, and particularly extensive experience in France, makes it appear that this may have been an isolated observation, however.

Nevertheless, the key problem remains the toxicity of the therapeutic agent—and there have been some doleful incidents (not at Hanford) to underline these reservations.

10. Symposia and Other Special Publications

a. Life Sciences Symposia

Beginning in 1962, the Hanford Biology Operation and its successor Pacific Northwest Laboratory sponsored annual symposia on subjects bearing on their research programs. These were not anniversary volumes, as in the case of the Utah symposia, and they cover a wider range of subjects. But a significant number brought together work and workers in the field of radioisotope toxicology. Like the Utah symposia, they provided many opportunities for review of local work, as well as national and international research. The symposia became more and more international, as did the reputation of the Laboratory, and many a delegate from the closely coupled countries of Europe had his first chance to appreciate why the Manhattan Engineer District chose this vast, still somewhat isolated site, to locate the plutonium production reactors.

A list of the Hanford symposia and their proceedings follows:

First Symposium—The Biology of the Transuranic Elements. 28-30 May, 1962, R. C. Thompson, ed. *Health Phys.* 8(6):561-780, 1962.

Second Symposium—The Biology of Radioiodine. 17-19 June, 1963, L. K. Bustad, ed. *Health Phys.* 9(12):1081-1426, 1963.

Third Symposium—Inhaled Radioactive Particles and Gases. 4-6 May, 1964, W. J. Bair, ed. *Health Phys.* 10(12):861-1259, 1965. Also published as hard-cover book by Pergamon Press.

Fourth Symposium—Radiation and Terrestrial Ecosystems. 3-5 May, 1965, F. P. Hungate, ed. *Health Phys.* 11(12):1255-1675, 1965.

Fifth Symposium—Swine in Biomedical Research. 19-22 July, 1965, L. K. Bustad and R. O. McClellan, eds. USAEC and Battelle Memorial Institute, 834 pp., 1966.

Sixth Symposium—Gastrointestinal Radiation Injury. 25-28 September, 1966, M. F. Sullivan, ed. Excerpta Medica Foundation, 542 pp., 1968.

Seventh Symposium—Diagnosis and Treatment of Deposited Radionuclides. 15-17 May, 1967, H. A. Kornberg and W. D. Norwood, eds. Excerpta Medica Foundation, Monographs on Nuclear Medicine and Biology No. 2, 681 pp., 1968.

Eighth Symposium—Myeloproliferative Disorders of Animals and Man. 20-23 May, 1968, W. J. Clarke, E. B. Howard, and P. L. Hackett, eds. USAEC Office of Technical Information Services. CONF-680529, 765 pp., 1970.

Ninth Symposium—Radiation Biology of the Fetal and Juvenile Mammal. 5-8 May, 1969, M. R. Sikov and D. D. Mahlum, eds. Div. Technical Information, USAEC CONF-690501, 1026 pp., 1969.

Tenth Symposium—Pollution and Lung Biochemistry. 2-5 June, 1970, D. B. Menzel, ed. Archives of Internal Medicine Symposia, Vol. 9, 282 pp., 1971.

Eleventh Symposium—The Biological Implications of the Transuranium Elements. 27-29 September, 1971, R. C. Thompson and W. J. Bair, eds. *Health Phys.* 22(6):533-954, 1972.

Twelfth Symposium—Radionuclide Carcinogenesis. 10-12 May, 1972. C. L. Sanders, R. H. Busch, J. E. Ballou, and D. D. Mahlum, eds. USAEC Office of Information Services, CONF-720505, 500 pp., 1973.

Thirteenth Symposium—The Cell Cycle in Malignancy and Immunity. 1-3 October, 1973, J. C. Hampton, ed. U.S. Energy Research and Development Administration, Office of Technical Information Services, CONF-731005, 605 pp., 1975.

Fourteenth Symposium—Radiation and the Lymphatic System. 30 September-2 October, 1974. J. E. Ballou, ed. U.S. Energy Research and Development Administration, Technical Information Center, CONF-740930, 258 pp., 1976.

Fifteenth Symposium—Biological Implications of Metals in the Environment. 29 September-1 October, 1975. H. Drucker and R. E. Wildung, eds. U.S. Energy Research and Development Administration, Technical Information Center CONF-750929, 682 pp., 1977. (Note: Only a few of the papers concern radioisotope metabolism.)

Sixteenth Symposium—Pulmonary Macrophage and Epithelial Cells. 27-29 September, 1976. C. L. Sanders, R. P. Schneider, G. E. Dagle, and H. A. Ragan, eds. U.S. Energy Research and Development Administration, Technical Information Center CONF-760927, 618 pp., 1977.

Seventeenth Symposium—Developmental Toxicology of Energy-Related Pollutants. 17-19 October, 1977. D. D. Mahlum, M. R. Sikov, P. L. Hackett, and F. D. Andrew, eds. U.S. Department of Energy, Technical Information Center, CONF-771017, 646 pp., 1978.

Eighteenth Symposium—Biological Effects of Extremely Low Frequency Electromagnetic Fields. 16-18 October, 1978, R. D. Phillips, M. F. Gillis, W. T. Kaune, and D. D. Mahlum, eds. U.S. Department of Energy, Technical Information Center, CONF-781016, 577 pp., 1979.

Nineteenth Symposium—Pulmonary Toxicology of Respirable Particles. 22-24 October, 1979. C. L. Sanders, F. T. Cross, G. E. Dagle, and J. A. Mahaffey, eds. U.S. Department of Energy, Technical Information Center CONF-791002, 676 pp., 1980.

Twentieth Symposium—Coal Conversion and the Environment: Chemical, Biomedical, and Ecological Considerations. 19-23 October, 1980, D. D. Mahlum, R. H. Gray, and W. D. Felix, eds. U.S. Department of Energy, Technical Information Center, CONF-801039, 607 pp., 1981.

Twenty-First Symposium—Biological Availability of Trace Metals. 4-8 October, 1981, E. A. Jenne and R. E. Wildung, eds. *Sci. Tot. Environ.* (special issue) 28:1-519, 1983.

Twenty-Second Symposium—Life-Span Radiation Effects Studies in Animals: What Can They Tell Us? 27-29 September, 1983, R. C. Thompson and J. A. Mahaffey, eds. U.S. Department of Energy, Technical Information Center, CONF-830951 (DE83016860), 1986.

Twenty-Third Symposium—Interaction of Biological Systems with Static and ELF Electric and Magnetic Fields. 2-4 October, 1984, L. E. Anderson, B. J. Kelman, and R. J. Weigel, eds. Pacific Northwest Laboratory, CONF-841041, 1987.

Twenty-Fourth Symposium—Health and Environmental Research on Complex Organic Mixtures. 20-24 October, 1985, R. H. Gray, E. K. Chess, P. J. Mellinger, R. G. Riley, and D. L. Springer, eds., Pacific Northwest Laboratory, CONF-851027, 1987.

Twenty-Fifth Symposium—Radiation Protection—A Look to the Future. 21-23 October, 1986, W. J. Bair, ed. *Health Phys.* (special issue).

Twenty-Sixth Symposium—Modeling for Scaling to Man: Biology, Dosimetry, and Response. 20-23 October, 1987, J. A. Mahaffey and J. A. Mewhinney, eds. *Health Phys.* (supplement).

b. Others

In addition to the yearly symposia, the Hanford people have, of course, organized and contributed to many other documents of interest to anyone tracing the development of internal emitter toxicology over the years.

A very early compilation was an "Official Use Only" report entitled *Plutonium Metabolism, A Literature Review* by J. Katz of the then-new Biology Division of the Health Instruments Division (Katz 1951). This contains tabular and descriptive summaries of the early work. The section headings herald most of the basic problems that have occupied our attention ever since. Fifty-eight references served to cover the highlights in those days!

A comprehensive review and commentary called "Biological Factors" for the handling of plutonium was prepared by Roy Thompson for the much-used "Plutonium Handbook," edited by O. J. Wick (Thompson 1967). In addition to over two hundred references, this chapter has very useful summary tables.

A volume with similar objectives was compiled by Roy Thompson and published in 1973 as a bibliography of the transuranium elements (Thompson 1973). This includes over one thousand literature citations. Three years later, a new edition contained sixteen hundred references, carefully selected (Thompson 1976).

Important compendia involving Hanford initiatives and/or participation bear especially on inhalation toxicology problems, as we shall see in chapter 9. We should add to these the lengthy summary-type documents prepared as testimony for the many hearings held by U.S. government agencies in the mid-1970s. These will be examined in due course, along with the roles played by the several large laboratories like Hanford in helping the Congress and the executive branches go through the agonizing process of trying to determine what is really known and what yet needs to be done after all the years of work and interpretations.

In the period from 1948 to the present, Hanford and its successor organization, PNL, has become one of America's prime centers for biological research involving radioisotope toxicology, both basic and applied.

B. Los Alamos Scientific Laboratory

1. Transition

During the years of World War II, there was no intention that the Los Alamos Laboratory would become a permanent installation. The single objective was developing an atomic weapon at the earliest possible moment.

In 1945–1946 many key personnel in physics and chemistry, including the wartime director, Robert Oppenheimer, departed. The buildings were of temporary-type construction and some of them fearfully contaminated. They would need either major reconstruction or replacement. Spirits were very low. Yet, the spark for continuation and extension was there. Thanks largely to Norris Bradbury who replaced Oppenheimer as director, Wright Langham who headed the health research, Ernest Anderson, and a few others, a viable core of dedicated personnel provided the basis for a comparative renaissance in 1946–1947 (Shipman 1969).

We saw in chapter 7 that Los Alamos was allowed to do very little biomedical research during the war, only work connected with the medical care of the workers (Hempelmann) and some studies of plutonium excretion in animals and man for purposes of bioassay (Langham). Oppenheimer was against having any biomedical research at Los Alamos. Let Chicago, Berkeley, Rochester, et al. provide that. Even the study of plutonium metabolism in patients, sparked by Los Alamos, had to be carried out elsewhere. Hempelmann and Langham had to fight hard to get whatever support they could during the war years. The size of the research operation can be judged by the size of the building that housed the Health Group in 1945. This structure is shown in figure 8.14A. Also shown is the building in which much of the plutonium chemistry and metallurgy was done (figure 8.14B). Realize that this was an improvement over the earlier facilities!

FIGURE 8.14A. View of the early biology facilities at Los Alamos commonly referred to as the "Rat House" or "Rat Lab." The wartime facility was smaller yet. (Photo courtesy of Dr. George Voelz, Los Alamos.)

FIGURE 8.14B. View of the “D” Building at Los Alamos in which much of the plutonium metallurgy and chemistry were done. Note that only some of the exhaust stacks are suitably far above the roof line. (Photo courtesy of Dr. George Voelz, Los Alamos.)

In the genesis of the Utah beagle experiment, the keen interest of the Los Alamos staff in getting much more information on plutonium toxicology was amply demonstrated. Even though Los Alamos was not the place for a king-sized dog experiment, there were many things the laboratory could do in the health sciences if the support were given. After a devastating review of safety at Los Alamos, particularly regarding ventilation, waste disposal, etc., by the newly created Safety and Industrial Health Advisory Board of the new AEC, the decision had to be made whether to go on and build up or scrub the operation. It was apparent to many at the time that the nation's security required continuation of a development laboratory like Los Alamos. The decision was made to build up. The so-called H-Division was created to include the former medical surveillance operation, more industrial hygiene and health physics, and related research. Advice regarding health and safety problems was sought from Philip Drinker at Harvard. Harriet Hardy, who had trained with Alice Hamilton,^(a) was loaned to Los Alamos in 1948 by the Massachusetts Division of Occupational Hygiene. Their influence brought Harry Schulte in to start a real industrial hygiene program. Tom Shipman was appointed as overall medical director in 1948. Harry Whipple had responsibility for the medical group. Wright Langham had the Biomedical Research Group and widespread interests and foresight.

(a) The legendary advocate for worker safety and a pioneer in occupational health.

Biomedical research expanded from plutonium to related elements such as americium (Shipman 1969). In the biochemistry group, some of the first syntheses of ^{14}C into biologically important molecules were accomplished.

With the program under way for real, a commodious Health Research Laboratory was constructed in 1952, followed in 1960 by an annexed animal facility. In general, the laboratory stuck to small animals and man insofar as internal emitter toxicology research was concerned. Through the foresight of Langham and Hempelmann, a nucleus of the wartime workers was earmarked for a prospective study of amounts of plutonium present and possible effects (more in chapter 16). Quite sizeable groups were also gradually developed in molecular and cellular radiation biology using primarily enzyme systems, cells in tissue culture, and microorganisms. The Health Division added considerable work in mammalian radiobiology using external radiation sources, included dogs and monkeys on occasion, plus an isotope application section. In later years, an environmental studies section was formed. Much thinking was done about approaches to the problems of inhalation toxicology, even though Los Alamos avoided the generation of aerosols by using microspheres bearing plutonium, as we shall see in chapter 9.

The H-Group numbered 125 in 1951–1952. By 1969, there were 260 personnel aboard. There was not a proportionate increase in the internal emitter research group. They made up for that, however, by having many of the most experienced and most dedicated personnel. What work was done with internal emitters was of very high quality. Some of that which is most germane to the subject of this chapter is reviewed in the following sections.

2. Actinide Research

While relatively small compared to the programs at Chicago, Utah, and Hanford, the Los Alamos work in the actinide field had a special quality. The medical follow-up of some of the Los Alamos plutonium workers has provided landmark information. Dr. Louis Hempelmann, who had been responsible medically for those workers during the war, continued as a central figure in this work, even though he had by then gone to the University of Rochester. Wright Langham and the medical group analyzed autopsy tissue for plutonium from the worker group. This included a victim of a criticality excursion who had been exposed over several years to plutonium aerosols (Foreman, Moss, and Langham 1960). The Los Alamos experience was written up in useful review papers such as those by Langham (1959) and Langham et al. (1962). Ten years later, a similar review encompassed several of the transuranium elements (Langham 1972).

In a more experimental vein, Langham and his colleagues published on the metabolism of plutonium in the rat, and Harry Foreman published a large number of Los Alamos reports and journal papers on therapeutic removal of plutonium from its deposition sites in bone.^(a) Included was a discussion of the mechanism of plutonium uptake by bone (Foreman 1962).

Langham, of course, continued his work on the kinetics of plutonium excretion with papers in the 1950s and 1960s (e.g., Langham 1957, 1964), which built upon the work described in chapter 7. A considerable polemic grew up around the virtues and defects of some rather small differences in formulation of

(a) All of the work on therapy will be considered separately in chapter 19 devoted to that subject.

excretion kinetics (Parker 1973). Some of the problem resides in the high variability of daily excretion rates (Snyder, Ford, and Warner 1968). While still at Hanford, Healy produced a classic paper (1957) on estimation of plutonium lung burden by urine analysis, a step beyond the estimation of body burden.

Since much of the nuclear weapons testing activity was generated at Los Alamos, it is not surprising that members of the H-Group became deeply involved with the biomedical implications of the tests. This included a very effective crusade by Langham on the implications of local area contamination with plutonium in the event of a nonnuclear detonation. Healy became interested in the movement of plutonium in soils and the problems of residual contamination, not only at the test sites in the continental United States and in the Pacific, but around industrial plants such as the one at Rocky Flats near Denver.^(a)

The Los Alamos staff also participated in depth in the Energy Research and Development Administration (ERDA) and the Environmental Protection Agency (EPA) hearings on the Liquid Metal Fast Breeder Reactor plans and other aspects of the so-called plutonium economy. As part of this, concern arose regarding possible genetic changes that might be induced by deposition of plutonium in gonadal tissues. This led to a valuable summary of most of the available information by Richmond and Thomas (1975) prepared just before Richmond left Los Alamos for Oak Ridge. This paper shows how minute is the concentration of plutonium and other actinides in gonadal tissue. Its abstract is given below:

This report summarizes available information on the gonadal content of mammalian species given various actinide elements by various routes of administration. Emphasis is placed on plutonium. Also discussed is the contemporary level of plutonium from nuclear weapons fallout in human subjects. The fraction of the administered burden of plutonium found in the gonads (FABG) of five mammalian species following intravenous injection was about 3×10^{-4} with only about a factor of 10 between the highest and lowest values to allow for differences between sexes, among species or as a function of time following injection. FABG values tend to be smaller in the female, as compared with the male, and following inhalation or subcutaneous implant. Data on the FABG for other actinides are qualitatively similar to those for plutonium. The gonadal plutonium concentrations from fallout in U.S. residents are about 0.5 pCi/kg, not unlike those reported for other soft tissues, except thoracic lymph nodes, and bone. (Richmond and Thomas 1975)

As part of a general attack on the biological response to small, discrete, highly radioactive sources, Richmond et al. (1968) fed 0.5 Ci of $^{238}\text{PuO}_2$ to beagles for six months. This was responsive to some of the concerns surrounding high-specific-activity heat sources for thermoelectric generators and also pertinent to the "hot particle" problem (cf. chapter 9). The effects on the gastrointestinal tract were relatively minor, although not zero. This agreed with findings at Hanford. An astonishingly large amount of insoluble alpha-particle-emitting radioactive material can pass through the gastrointestinal tract with little damage, either structural or functional. Work with rat lung was reported by Richmond, Langham, and Stone (1970). (More in chapter 9.)

In 1974, the Los Alamos group sponsored a major symposium on actinide research (Healy 1975). Much of it was aimed at problems of plutonium in man and problems of standard-setting generated by ferment regarding plutonium

(a) We will review the problems of nonnuclear detonations and general area contamination with plutonium in chapter 14, and general problems of isotope transfer in the environment in chapter 15.

standards developed in the hearings on breeder reactors. A typical example of the subject matter can be found in a paper by Stannard (1975a). The Los Alamos contributions, besides the planning and hosting, were, as usual, quite directly concerned with the applied problems.

3. Tritium

The Los Alamos contributions to tritium research were much like those from Hanford, i.e., more or less directly connected with daily problems in the work of the laboratory, including the development of fission-fusion weapons. While much of the work with tritium concerns environmental distribution and effects, or its embodiment into cells and biomolecules, an early Los Alamos study went directly to its metabolism in man. An Air Force officer, Dr. E. A. Pinson, was assigned in 1950-1952 to Los Alamos primarily to help with some biomedical aspects of the nuclear weapons testing program. But he found time to join with Wright Langham in some definitive laboratory research. Not by coincidence, Pinson had done a Ph.D. thesis at Rochester on water balance in man and knew already both the techniques and the problems.

This work showed in man the very rapid exchange reactions that the Hanford people were in the process of establishing in animals. Also, Pinson and Langham (1957) established that tritium (as HTO) passed inward through the skin at a rate comparable to that of insensible perspiration moving outward, a finding of immediate importance to maximum allowable exposures. The substance of this important paper can be gleaned from its abstract, reprinted below:

Using tritium water as a tracer in man, water absorption through the gastrointestinal tract began in 2-9 min and was complete in 40-45 min. The volume of water transferred from the intestine to the blood was linear with time and proportional to the volume of water ingested, within the range of 100-1000 ml. When exposed to HTO vapor via inhalation, man absorbed through the respiratory system 98-99% of the activity inspired. The activity in venous blood increased sharply during and shortly after inhalation exposure, after which it declined exponentially to equilibrium with a half-time of about 12 min. The average dilution volume in five experiments on three normal males was 62.2% and the biological half-time of tritium in body water of eight males on ad libitum water intake averaged 11.5 days. At equal vapor pressures man absorbed HTO inward through the skin at a rate comparable to the rate of insensible perspiration. HTO appeared to diffuse across the inert barrier of the outer skin with a half-time of about 3 min. When man was exposed to an atmosphere containing HTO, the HTO entering the body through the total skin area was approximately equal to that entering through the lungs. Both man and rat slowly oxidized inspired HT to HTO. The radiation hazard from exchange of tritium with hydrogen of the tissues after chronic or acute exposure to HTO was small compared to the hazard from the amount of HTO necessary to induce the activity into tissue components. On the basis of human data, the maximum permissible body burden of tritium was calculated to be 3.7 mCi, and the maximum permissible concentrations of tritium oxide in air and water for continuous 24-hr exposure was estimated at 5×10^{-6} μ Ci and 0.1 μ Ci/ml, respectively. Adoption of the 1956 recommendations of the International Commission of Radiological Protection will result in the division of the above values by three.
(Pinson and Langham 1957, reprinted in 1980)^(a)

(a) This paper was selected as a "landmark paper" to be reprinted in the silver anniversary issue of *Health Physics*.

Other papers from Los Alamos bearing on this same subject concerned the specific activity of tritium in the organic components of skin (Pinson, Anderson, and Lotz 1952) and the biological effects of inhalation of high concentrations of tritium gas (Trujillo, Anderson, and Langham 1955). Collaboration of other staff, such as C. R. Richmond, came slightly later. Special note should be made of the fact that, although the publication dates are in the mid-1950s, the work on man was done quite early in the postwar era.

An experiment of special interest, indeed almost unique, is one on the RBE^(a) of the beta particles from tritium relative to ^{60}Co gamma rays (Furchner 1957). There have been hundreds of RBE determinations comparing one external radiation source with another.^(b) But when one of the radiations comes from an incorporated radioisotope, the situation becomes very complex because the metabolism (i.e., pharmacokinetics of the radioisotope) may result in dose rates that change rapidly with time if the isotope has a short half-life, is eliminated rapidly, or both. Furchner arranged the external radiation source (^{60}Co) inside a lead shield machined to produce an exponentially decreasing dose comparable to the declining dose from tritium as HTO by slow movement of the source within the shield. This ingenious device is shown in figure 8.15.

Using thirty-day mortality in CF1 mice as the criterion and the intercept constants from probit mortality curves, Furchner calculated an RBE of 1.72 ± 0.13 . It happens that this value agrees with others obtained without the special effort to match dose kinetics and with varying criteria (e.g., Thompson 1954; Storer et al. 1957; and Los Alamos Scientific Laboratory reports in 1953 and 1954). But the RBE values are so small anyway that this may not have been the best test system for analysis of the point at issue. Nevertheless, the point is important. While Sacher (1954) appears to have had some interest in what he terms the lethality function for exponentially decaying exposures, there does not seem to have been as much general application of this

FIGURE 8.15. Lead shield for exponential exposure of CF1 mice to Co^{60} γ -radiation. (Redrawn from Furchner 1957. Reprinted with permission of Academic Press, Inc., Orlando, Florida, copyright 1957.)

(a) See discussion of this terminology on page 387.

(b) Los Alamos was a center for such work. Witness an over-one-hundred page paper by the Los Alamos staff in 1957 (Storer et al. 1957).

idea as might be expected. Obviously, when half-lives and/or retention are quite long, there is little hope of obtaining a conventional RBE between an internal emitter and an external source, unless the external exposure is very long term. Nevertheless, it is surprising that more work has not been done in this area after Los Alamos showed the way. It might have particular pertinence in cases where a component of chemical toxicity from the radioelement is suspected. Elimination of any dose-rate factors would be essential in such cases.

4. Fission Products and Other Radioisotopes

It was natural that, despite the plethora of work around the country on fission products and fallout, the Los Alamos Health Group should get deeply involved. Much of this work is more pertinent to chapter 13, where it will be reviewed. But some is of quite general significance and should be reviewed now.

Central to this is work organized by Chester W. ("Chet") Richmond during his years at Los Alamos. With his colleagues Furchner, Drake, London, Thomas, and others, a systematic study was made of the comparative metabolism of radionuclides in mammals. In contrast to the king-sized long-term experiments going on elsewhere, the Los Alamos work built upon a series of discrete experiments. There were several animal species and several routes of administration in each study.

Part of the importance of this work was the methodology. The Los Alamos people built one of the early whole-body counters using photomultiplier tubes and a large volume of liquid scintillation fluid (see chapter 17). They also built scaled-down versions suitable for doing whole-body counts on small animals. In the early work, this was called simply "Small Animal Counter." Later, this type of device was called "LASAC I," while the larger device in which large animals and humans were measured was called "HUMCO I." A diagram of the small animal device is shown in figure 8.16.

FIGURE 8.16. Small animal counter, Los Alamos Scientific Laboratory. (Redrawn from Woodward, Richmond, and Langham 1956.)

The system provided extremely sensitive 4π -steradian geometry. Thus, very small amounts, truly tracer amounts, of the radionuclides could be employed, and adequate data could be obtained over reasonably long periods. Also, a few of the elements were administered, in very low doses, to man so that extrapolation to man could be checked by real data points on man.^(a)

Equations for retention in the whole body as a function of time were derived by computer techniques. In nearly every case, the data could be fitted by one to three exponential terms, seldom by a power function. (Remember the Chicago work discussed earlier applied a power function to some of the bone-seeking elements.) Special attention was given to the longest-term component because of its pertinence to the occupational exposure guides. By taking the integral of the individual effective^(b) retention functions from time zero to time infinity, an entity called the metabolic equilibrium factor could be derived. This expressed the relation of the final equilibrium body content for that particular species and the particular route of administration to the unit dose, i.e., daily intake, assuming intake was quasi-continuous as postulated for deriving the exposure limits. In nearly every case, this factor increased with body weight. A general relation of the form:

$$E. F. = a (\text{body weight})^k$$

where E. F. is the Estimated Equilibrium Factor expressed as a multiple of the daily dose; and the constants a and k are derived from least-squares fits of the data to regression lines.

In most cases, this relation was linear. It was complex for ^{60}Co , i.e., the whole-body retention appeared to be longer in mouse than in the rat, monkey, or dog. This latter was attributed to species differences in the behavior of vitamin B_{12} , of which cobalt is a part. In general, this relation to body weight supported extrapolation to humans and estimation of MPC^(c) values from the extrapolated animal data.

The first report in this systematic study was in a paper given at the first meeting of the Health Physics Society (Woodward, Richmond, and Langham 1956). It concerned ^{24}Na , ^{42}K , ^{86}Rb , and ^{134}Cs given orally or intravenously. The subjects were rats, mice, and a single human volunteer for the cesium experiment. The elements used obviously ranged from some of primary interest to the physiology of electrolytes, through some of interest because they are fission products or activation products, to some included because of their general importance in toxicology.

The bulk of the work was set out in eleven papers entitled, "Comparative Metabolism of Radionuclides in Mammals," all published in *Health Physics*. An overview of the series is given at the top of page 458.

How the body-weight-equilibrium-factor relationship worked out for four elements is given in figure 8.17A, B, C, D.

(a) As Richmond stated (1979), they felt that unwillingness to accept personally administration of isotopes at levels well below the allowable limits would imply lack of confidence in those limits. Some of this was before the As Low As Reasonably Achievable (ALARA) principle had been adopted.

(b) Effective, meaning that both physical decay and biological elimination were included.

(c) Maximum Permissible Concentration, the parameter used until very recently for expressing allowable intakes of radioelements.

Paper No.	Element	Animals	Routes of Administration(a)	Reference

FIGURE 8.17D. Interspecies correlation between ^{70}Be equilibrium levels (estimated from single oral doses to mice, rats, monkeys, and dogs) and body weights. The broken portion of the curve is an extrapolation to a 70-kg body weight. (Redrawn from Furchner, Richmond and Drake 1968. Reprinted with permission of Pergamon Press, Ltd., Elmsford, New York, copyright 1968.)

The cases where the equilibrium amount is close to or even less than the daily dose represent either very poorly absorbed or very short half-life elements, while high equilibrium levels result when the converse is true. The equilibrium factor (E.F.) will, of course, be a function also of the route of administration and may be very different after intravenous administration of an element that is poorly absorbed from the gut since the E.F. is expressed as a product of the daily dose. This can be seen in the tables of several of the papers.

Special note should be made of the following findings:

1. The whole-body retention of iodine is about equally divided between thyroid and pelt. It is customary to think of the burden as wholly in the thyroid because of its high concentration there.
2. The differential of the retention curves can be used to express excretion rate.
3. Parabolic relations between species weight and daily turnover are quite general for mineral metabolism both in this study and in the literature. Similar relations hold for other physiological processes.
4. The same element can require different numbers of exponential terms to express retention after different routes of entry.
5. Cobalt is the maverick in this particular series. The data for the rat fit a logarithmic plot, i.e., a power function (Richmond and London 1968) and so can the data from the mouse. But the monkey and dog do not show any decrease in rate with time.
6. Many of the calculated MPC values agree well with the then-current ICRP-NCRP numbers. Others are at variance by factors from two to five or more. The same goes for parameters like gastrointestinal-tract absorption. But only in the case of cobalt would extrapolation from rodent data to man be seriously misleading (more in chapter 16).

Richmond (1979) states that these isotope metabolism figures from Los Alamos were given special credence by those (e.g., Walter Snyder et al.) seeking biological input data for the MPC calculations of ICRP and NCRP. This was because

the very low levels ensured no component of chemical toxicity or radiation damage in the results.

There were other papers correlated closely with this series but not numbered in it. These, plus some abstracts for meetings (e.g., Richmond, London, and Furchner 1964), sum to a very useful and sophisticated set of contributions to our understanding of the metabolism of many elements.

More of the Los Alamos work on fission products will be reviewed in consideration of the research specifically oriented toward the problems of fallout (chapter 13).

5. Comment

These few pages, devoted as they are to postwar work only on the actinides, tritium, and to fission products, can give only a cursory idea of what developed in the Health Sciences at Los Alamos between 1949 and the 1970s, particularly since two major areas of direct pertinence to internal emitter research have been postponed for the most part to later chapters. The "hot particle" problem occupied much of their attention but is more appropriately reviewed in connection with inhalation toxicology. Much of their participation in nuclear testing, environmental contamination, development of a nuclear-propelled rocket, radioisotope heat sources, etc., is deferred for later discussion. And, finally, it takes only a cursory glance at a typical annual report to see that the laboratory engaged in a large amount of work with external sources and full-fledged programs in molecular and cellular radiobiology. Yet, the names we immediately associate with Los Alamos in the postwar years are of those who had most to do with the internal emitter research: Wright Langham, E. C. Andersen, Jack Furchner, Chet Richmond, Jack Healy, Harry Schulte, Tom Shipman, Robert Thomas, and George Voelz, in situ, and Louis Hempelmann acting partly in situ and partly from Rochester.

V. Other U.S. Work

Postwar biomedical work on the fission products and actinides in the United States has now been reasonably thoroughly reviewed in this chapter, except for those topics put over for later discussion. Some laboratories that were active in the field during the war years (e.g., Rochester) concentrated on other areas and/or basic work not generated by the specific problems of any particular element. Others entered the field for a relatively circumscribed, yet significant, enterprise. This section will review very briefly some of these activities. They are not all laboratory research; but all are pertinent.

A. Colorado State University

The Department of Radiobiology and Radiology at Colorado State University (CSU) has been operating a large barrier-maintained beagle colony primarily for studies of external radiation effects as a function of age. This was supported initially by the U.S. Public Health Service and by later-spawned agencies. They also have had interests in the uranium miner problem, in environmental pollution, and have had a strong graduate teaching program.

Apparently because of their close proximity to the Rocky Flats plutonium plant, they undertook work directly related to entry of plutonium into the body via wounds. Some of the work was collaborative with the Rocky Flats staff. They

implanted samples of "high-fired" PuO_2 (calcined at 850°C) and of plutonium nitrate in the left foot pad of the dog. They then measured translocations, effects of chelating agents, and the relative behavior of ^{241}Am from the decay of ^{241}Pu . Indeed, they used the x ray from this isotope to help measure the translocation.

One of the early papers from this group was a report of lymphoma developing in the regional lymph nodes of a dog receiving air-oxidized plutonium by subcutaneous injection (Lebel et al. 1970). Most of the rest of the work concerned metabolism of the plutonium from implanted sources.

In a paper given at the Hanford symposium on transuranium elements in 1971, Watters and Lebel (1972) summarized the metabolism work. The abstract is given below:

Air oxidized plutonium, $\text{Pu}(\text{NO}_3)_4$ and high fired PuO_2 (850°C) which had known amounts of ^{241}Am were implanted over the left metacarpus in beagle dogs and the concentrations of ^{239}Pu and ^{241}Am in various tissues were measured as a function of time. The effect of DTPA therapy upon organ depositions was also studied.

For air oxidized plutonium, rapid movement of ^{239}Pu and ^{241}Am to the proximal lymph node (superficial cervical) has been observed by in vivo counting. Approximately 3% of the implant material reached the lymph node within 2 weeks and continued an exponential build-up to 17% at 1 yr.

Results of plutonium assays in blood indicate a 14-fold increase in movement to the circulation from the $\text{Pu}(\text{NO}_3)_4$ implants as compared with the air oxidized plutonium. This is supported by comparison of the depositions in the liver and the proximal end of the femur where the $\text{Pu}(\text{NO}_3)_4$ experiment produced twenty-four times higher levels of plutonium than did the air oxidized plutonium experiment.

The effect of DTPA therapy was greater for the nitrate than for the air oxidized plutonium implants. (Watters and Lebel 1972)

Bistline, Watters, and Lebel (1972) compared the translocation dynamics in the same system of americium and plutonium in two forms. They comment especially on the accumulation in the proximal lymph node(s) and differences between this and experiments done two years earlier by Johnson and Watters (1970). (a) In the 1972 experiments, the lymph nodes reached a peak concentration at about fifty days, then fell off again, while in the earlier work build-up continued throughout the one-year study. The particle sizes of the implanted material were considerably larger in the earlier experiment, and this is taken as an explanation for the difference.

Of considerable significance to any prognosis of systemic build-up from wounds was the finding that the speed of initial translocation depends more upon the position of the implant than on the amount of plutonium present.

A third paper at the same symposium (Gomez, Lebel, and Watters 1972) looks at the effect on the translocation of excision of a cervical lymph node on the side of the implant. Even though it was clear that other lymphatic nodal tissue remained, the result was an increase in plutonium levels in liver, spleen, and hepatic lymph nodes. The authors comment on the advisability of removal of lymph nodes in cases of human contamination by wounds. The rationale for this seems somewhat shaky since it might not necessarily be better to have more plutonium in liver and spleen in lieu of an amount in a peripheral lymph node.

With this problem partly in mind, Gomez, Lebel, and Watters (1972) tried delaying the removal of the lymph nodes until fourteen days. In this way, they

(a) Rapid movement to lymph nodes was first shown in this report.

expected to be able to remove significant amounts of plutonium and perhaps not stimulate translocation of the remainder. There was indeed a "large amount" of plutonium in the excised lymph nodes, but transfer to liver, spleen, and hepatic lymph nodes increased significantly nevertheless.

Although the CSU group has continued active in many aspects of environmental contamination with plutonium, the type of work involved above does not seem to have gone much further there.

B. New York University Institute of Environmental Sciences

This organization has had a significant impact on internal emitter toxicology. Nearly all of the work pertains to either inhalation toxicology, environmental pollution, or elements such as radon and its daughters, polonium, uranium, thorium, etc., which we have already reviewed. The exception is some work with americium and curium in man and the baboon. For many reasons, it is more convenient to take up these transplutonic elements as a group in the final section of this chapter.

C. Oak Ridge Institute of Nuclear Studies and University of Tennessee

For many years, two aspects of the postwar work on fission products and actinides were pursued in depth under the general aegis of the rather loosely organized Oak Ridge Institute of Nuclear Studies (ORINS) (see Appendix B).

1. The University of Tennessee-Atomic Energy Commission Farm (UT-AEC Farm)

This "farm" and associated laboratory were developed initially as a holding operation for cattle and other large animals exposed to fallout from weapons tests. An extensive experimental program was developed under the direction of Dr. Cyril Comar until he moved to Cornell. In later years, Dr. T. R. Noonan managed the research program. For some years, its output and financing were funneled through the Oak Ridge Institute.^(a) All of the work bore on fission products in animals, plants, and the environment. For convenience, it will all be regarded as work stimulated by the problems of fallout and be discussed in chapter 13. But it contributed much to understanding the basic behavior of these elements in large and small animals as well as in plants and ecosystems. For this reason, it needs to be recognized here even though specifics are deferred.

Also to be recognized here but discussed in connection with contributions to basic science is the work on radiocolloids done by G. K. Schweitzer at the University of Tennessee (e.g., Schweitzer and Jackson 1952).

2. Medical Division of Oak Ridge Institute of Nuclear Studies

We reviewed in section II B the systematic study of the lanthanides at Berkeley. We also cited the general compendium on rare earths gathered together by Granvil Kyker of the Medical Division of ORINS. Probably no other single laboratory has looked as hard at or made as many trials for possible applications

(a) In more recent years, it has become the Comparative Animal Research Laboratory (CARL). Other key staff members are mentioned in chapter 13.

in nuclear medicine of radionuclides in the lanthanide-rare earth series. In the process, they engaged in much background work on the behavior of these elements, both in vitro and in vivo in animals (Kyker) and man (Andrews). There was collaboration with the Spedding group at Iowa State University in obtaining and characterizing the compounds required. Since the primary thrust of this work is in the field of nuclear medicine, the background as well as the clinical work will be reviewed briefly in the chapter on that subject (chapter 20).

D. University of Rochester

It should be apparent from other chapters (1, 2, 3, 4, 9, 10, 14, 19) that the postwar work at Rochester with uranium, radium, radon and its daughters, polonium, and many miscellaneous nuclides whose toxicity needed study had deep significance for all of the problems of internal emitter toxicology. But the wartime work with plutonium did not continue except for inhalation studies.

The only major experiment at Rochester within the purview of this chapter was work sparked by Lawrence W. Tuttle on ^{90}Sr in monkeys with spill-over work in rats. The animals imbibed the isotope in the drinking water in the case of rats, by gavage in the monkeys. Hence, the experiment was comparable to, although smaller than, those with swine at Hanford and with dogs at Davis. The primary novel feature was use of a primate as well as the rat. In this it paralleled the effects phases of the work at Berkeley on primates.

The methodology was given in a University of Rochester report (Tuttle et al. 1959), pathology in rats by Casarett et al. (1958), and the late pathology in both rats and monkeys by Casarett, Tuttle, and Baxter (1962). This last report is full of detail on the rodent, which can be reviewed better along with other effects experiments in chapter 13. Let it be said here, however, that there were only seven monkeys in the experiment. These were at two dosage levels, 500 μCi (three monkeys) and 1,000 μCi (four monkeys). Body burden at death ranged from 33 to over 200 μCi . The cause of death was given as parasites in two animals, one at each dosage level, as pancytopenia in one of the higher-dose animals with a calculated skeletal dose of 4,500 rad, and as leukemia in one of the lower-dose animals with a calculated skeletal dose of 4,300 rad. Only two, both in the higher-dosage group, died with tumors of the type usually attributed to ^{90}Sr deposition in bone. One was a chondrosarcoma in an animal with 9,500 rad calculated skeletal dose. The other was an osteosarcoma in a monkey with a calculated dose of 4,700 rad.

It appears that most of the pathologic effects in this work were gleaned from the Long-Evans rats.

Another piece of work of pertinence is a study of the renal excretion of strontium and calcium in dogs by Della Rosa, Smith, and Stannard (1961). This work indicates that there is discrimination toward calcium retention and away from strontium retention by the dog kidney. (More in chapter 13.)

Of special interest to the theoretically inclined is the analysis by Blair (1968) of radiation dose-time relations for induction of bone and skin tumors. From a kinetic analysis of already published data, he postulates that there are two mutually exclusive routes of tumor induction in both rat skin and dog bone. The skin received brief doses of beta radiation, while the bone doses were from injections of ^{239}Pu , ^{226}Ra , ^{228}Ra , or ^{228}Th , all alpha emitters. The radioisotope data were primarily from the Utah experiments, the beta exposures of skin in rats from work of Albert and colleagues at New York University. As Stannard lamented

earlier (1973), these ideas could now be tested with longer-term, more secure data, but Harry Blair is not here to do it, and others have not picked up the thread.

Incidentally, a toxicity ratio could be calculated from the values of "K," the so-called initiating dose for the various elements. It comes out quite close to the ratios we have already become familiar with: using ^{226}Ra as the standard, the ratio for ^{239}Pu is 7, for ^{228}Ra is 1.7, and for ^{228}Th is 4. The analysis also provided a factor for time to develop a tumor. But this was not so amenable to analysis. General summaries were written by Stannard (1973, 1975b).

E. Other Laboratories and Organizations

Despite the length of this chapter, the biomedical work done at U.S. laboratories since World War II on actinides and fission products is far from being completely cited. Since the reader may wish to know what went on at a few laboratories not included above, some additional remarks are needed.

1. Cornell University

Cornell University developed, at about the middle of the period covered by this chapter, a laboratory of Physical Biology as part of its Veterinary College. Dr. Cyril Comar moved up from Oak Ridge and assembled a staff with interests in mineral metabolism. The *modus operandi*, at the outset at least, was a continuation of the broad studies on fission product movement in animals and plants, and to a lesser extent effects started at the UT-AEC Farm in Oak Ridge. Interspersed was a gradually increasing amount of work bearing on mineral metabolism *per se*. It is to our advantage to view the details of the Cornell work in chapter 13 along with other work stimulated by the problems of fallout.

2. Oak Ridge National Laboratory

a. Biology Division

The Biology Division of Oak Ridge National Laboratory stayed clear of radioisotope toxicology, as defined for this book, until almost the end of the period of this chapter. In the midseventies, a collaborative effort between Argonne National Laboratory and the Oak Ridge Biology Division in the field of genetics began. All through the years of the Russells' "megamouse" experiment using external radiation, there had been concern about possible genetic effects of internally deposited radionuclides. But data were limited to single-cell or colony systems, to measurements of chromosomal aberrations, and to assay of gonadal content (e.g., Richmond and Thomas 1975; Brooks, personal communication) of important elements for calculation of dose. The effects studies were summarized, for example, in reports from Argonne (Grahm et al. 1979), from Lovelace (Brooks 1975), and in work done abroad.

Recently the Russells' powerful specific locus mutation technique was applied to mice injected with ^{239}Pu citrate. The dose was $10\ \mu\text{Ci/kg}$ body weight or about $0.25\ \mu\text{Ci}$ per mouse. The plutonium was in monomeric form. The solutions were prepared and injections performed by Argonne personnel (Arthur Lindenbaum and later Douglas Grahm).

Only one publication has appeared to date concerning the results of this work, an abstract by Russell et al. (1978). This showed that a highly significant

increase in mutation frequency was produced by this dose of plutonium. The workers are in process of gathering sufficient data to provide an adequate estimate of the genetic hazard of plutonium.^(a)

b. Health Physics Division

The Health Physics Division at Oak Ridge National Laboratory has been the mecca for the problems of internal dosimetry and the derivation of intake limits for radioisotopes; as we shall see in chapter 16. They have also made occasional forays into experimental work, as we saw in the chapter on uranium, and will see when we discuss work such as that by Isabel Tipton aimed directly at the determination of parameters to be entered into the dosage calculations.

3. Health and Safety Laboratory, New York (Environmental Measurements Laboratory)

The USAEC Health and Safety Laboratory (HASL) in New York City (now the Environmental Measurements Laboratory) has made significant contributions to research on fission products and actinides. Researchers there took special cognizance of methodologies; they have been extremely active in measuring and evaluating environmental contamination, both from fallout and from civilian nuclear operations; and they have provided important support for a large number of monitoring and radiation safety evaluations of specific sites. It is appropriate to reserve the details for the chapters on fallout and the environment and the practical problems to be reviewed in chapter 16. In general, their contributions were accessory to internal emitter toxicology as we are reviewing it, but they have made much of the research better and more responsible to problems in the field. Also, individuals from the HASL staff have been deeply involved with many research projects domiciled in other places.

4. University of California, Los Angeles

An AEC project was developed at the University of California, Los Angeles (UCLA) after the war years, patterned much after the Rochester Project that Stafford L. Warren had helped to initiate in the MED days. The UCLA project has been deeply involved in biomedical aspects of the weapons testing program, especially environmental contamination, in nuclear medicine, and in basic radiobiology. It also has had an active educational program. The work associated with the weapons tests and fallout, and the later environmental work will be reviewed in chapters 13, 14, and 15; the work in nuclear medicine in chapter 20. The rest is outside our purview.

5. U.S. Atomic Energy Commission, Division of Biology and Medicine; U.S. Energy Research and Development Administration, Division of Biological and Environmental Research; U.S. Department of Energy, Office of Health and Environmental Research

That the role of the "Headquarters" scientific staff was much more than administrative should be obvious from the numerous references already made to their

(a) Unpublished observations supplied to the author as part of his functions with the National Council on Radiation Protection by A. L. Brooks, the Chairman of a special Task Group on Genetic Risk from Internal Emitters, indicate that, for the present, the hazard can be considered comparable to an equivalent dosage from external radiation.

work in specific areas. Many more such references will be made as we proceed. But the field of fission products and the actinides came in for especially intensive attention from within the Headquarters operation.

When Ernest Sternglass began his series of allegations on excess infant mortality resulting from the release of fission products from weapons tests and later from power reactors, the Headquarters staff had to do much more than get and coordinate opinions. They became the vortex for much of the polemic. We shall review this saga in chapter 12.

In the actinide field, the Headquarters staff was responsible for several activities of wide scope and considerable depth to evaluate the status of our knowledge. Much of this was forced by the breeder reactor concept, the prospect of greatly increased amounts of plutonium and other actinides in the nuclear industry, and potentially in the environment, and the public reactions to these.

The first action occurred near the end of the existence of the AEC. It consisted of the development "in house" of a series of Plutonium Task Forces responsive to a Plutonium Committee. The central problem was the defensibility, or lack of it, of current MPCs for plutonium and other transuranic elements. But the documents ranged over all of the research in the area.

The second developed early in the ERDA period. It included a large workshop in 1977 at the Battelle Seattle Research Center to address the current research needs in actinide biology. This was organized by Dr. Patricia Durbin from UCRL-Berkeley. There were summary presentations by a considerable cross section of the research community who had been admonished by the Chairman to "Think Actinides." There followed an executive session in which the Headquarters staff used the information presented, as well as background material, to help shape recommendations for ongoing programs. The summary of actinide biological research, 1943-1977, prepared for this meeting by Durbin is especially useful for historical perspective. It is available as Appendix A to CONF-770491 (Durbin 1978b). Naturally, the details of the executive session have never been made available, since they involved decisions regarding specific programs and people. We might have heard more of the decisions if ERDA had not been reorganized, with staff changes, to become part of the Department of Energy (DOE) soon after these events.

A third effort of more than routine dimensions was an internal emitter advisory committee in the Division of Biomedical and Environmental Research of ERDA. This group, which was something of a moving target, stimulated summaries of the work supported by ERDA on metabolism, dosimetry, and effects of transuranium and transplutonium elements and specific recommendations for continued or new work on these as well as other radioisotopes. Frequently, the opinions of outside consultants were folded into the eventual documents or attached as supplements.

Details of the reports are presumed to be proprietary since they were strictly "in house" documents.^(a) Yet, some of the ideas found in them brought into focus neglected as well as overworked areas. In the present context, let it be

(a) The author had the privilege of rummaging through numerous files concerning these activities during one of several visits to the current Office of Health and Environmental Research in the Department of Energy. Thanks are due especially to Dr. William J. Burr and his secretarial staff for making the process relatively easy.

said that these activities at Headquarters frequently added essential information or essential perspective that kept support flowing for laboratory and field activities or arranging gradual termination.

Finally, the Headquarters staff wrote hundreds of pages of documents for the epidemic of hearings in the mid-1970s, sponsored especially, but not exclusively, by the EPA and the Nuclear Regulatory Commission (NRC), as well as by ERDA and DOE. Documents that summarize internal emitter research are cited from time to time in connection with specific areas.

6. Federal Radiation Council

The Federal Radiation Council (FRC) will be described in chapter 16 since it was concerned primarily with standard-setting. It, like the AEC and ERDA, stimulated many reviews and evaluations. Some were done earlier than the activities described in the previous section. They were accomplished largely by bringing in advisory groups or asking the National Academy of Sciences (NAS) to prepare evaluations.

One evaluation with the most pertinence to the subjects of this chapter is a report dated December 1964, by an NAS Advisory Committee to the FRC (NAS-FRC 1964). This was a full review of all aspects of the implications to man from internally deposited ^{89}Sr , ^{90}Sr , and ^{137}Cs . The report considers radioactive cesium like whole-body exposure and lists the chief concerns as genetic damage, leukemia, and other neoplasms, while the localized strontium exposure to bone and bone marrow is considered prone to produce leukemia and disturbances of growth and development of the skeleton and teeth, in addition to producing bone tumors. The section on genetics takes special pains to consider findings since the National Academy-National Research Council BEAR (Biological Effects of Atomic Radiation) reports in 1956 and 1960. In general, the estimate of genetic risk was regarded as being reduced by the new work. The report also summarizes genetic studies on strontium isotopes done abroad.

7. National Council on Radiation Protection and Measurements

The NCRP, a Congressional charter organization,^(a) is primarily organized around promulgating recommendations for allowable radiation exposures or intakes of radioactive materials. But increasingly it has also been publishing reports that are state-of-the-art summaries of their subject fields. They also issue timely summaries of measurement techniques.

Reports with direct bearing on postwar fission product or actinide research concern ^{85}Kr in the atmosphere (NCRP 1975); tritium measurement techniques (NCRP 1976); ^{137}Cs from the environment to man: metabolism and dose (NCRP 1977); physical, chemical, and biological properties of radiocerium relevant to radiation protection guides (NCRP 1978); and tritium and other radionuclide-labeled organic compounds incorporated in genetic material (NCRP 1979). Other reports were or will be cited with the relevant subject matter (e.g., chapter 3, chapter 16).

While these reports bring together much of the experimental work with a bearing on the development of standards, they also address most of the basic questions and problems remaining to be solved.

(a) More history of NCRP in chapter 16.

VI. Work Abroad

The charter for this book (see foreword) puts severe constraints on the amount of space that can be devoted to work in other countries. Even if it were not the intent to focus primarily on the work of the MED, the AEC, and successor organizations, the mass of material on fission products and the actinides worldwide would overwhelm us if we attempted any detailed review. Yet, there was not only a considerable volume of work abroad, it was, much of it, of such high quality that total omission could not be contemplated.

Soon after World War II, the United Kingdom, Canada, France, and the Soviet Union developed nuclear energy resources with great dispatch. Along with this came biomedical research. Some of it duplicated almost exactly work that had been done in the earlier American operation. This can be ascribed partly to the time required for declassification and publication of the U.S. war work. Also, it represents partly the desire of each laboratory to apply its own idiosyncratic approach or the special nature of its field problems.

Other countries, such as Austria, Belgium, Czechoslovakia, Denmark, India, Italy, Japan, the Netherlands, Norway, Poland, South Africa, Sweden, Switzerland, and West Germany either expanded on activities they already had going or built research programs as needed. The U.K., French, and Soviet work were the most extensive.

Particular interest attaches to the following from the United Kingdom:

1. Actinide and strontium work at the Medical Research Council's (MRC) Bone Research Laboratory at the Churchill Hospital, Headington, Oxford, where Dame Janet Vaughan, Betty Bleaney, and associates did wide-ranging studies with the bone seekers in rabbits. Results paralleled U.S. work in general. There were many opportunities to exchange ideas and results. The chief difference seems to be a larger role of soft-tissue changes in the rabbits and, because of this, changes in the thinking of this group.
2. Basic chemical and biochemical reactions of actinides with constituents of blood and bone by David M. Taylor and A. R. Chipperfield at the Institute for Cancer Research, Sutton, Surrey, wherein the transport of plutonium as a complex with ferritin was nailed down.
3. Questions of bone modeling and the target cells in bone by F. W. Spiers at the Department of Medical Physics, University of Leeds.
4. Much metabolism and mechanism work at the MRC Radiological Research Unit at the Atomic Energy Research Establishment at Harwell (J. Vennart, J. F. Loutit, R. H. Mole, et al.). This included deposition in gonads and cytogenetic studies.
5. A broadly based summary of plutonium toxicology from the MRC Headquarters.
6. Short, yet significant and timely commentaries on both broad and specific problems from the Radiological Protection Service and Board at Sutton, Surrey.

Much of the U.K. work is cited in books and chapters prepared by U.K. authors and referenced in this and other chapters in connection with specific topics. Special mention should be made here of the book on strontium metabolism edited by Lenihan, Loutit, and Martin (1967) and on low-level irradiation with emphasis on strontium by Loutit (1962), as well as the comprehensive

reviews of Vaughan (1973) on plutonium in the skeleton, by Taylor on the chemistry of plutonium (Taylor 1973a) and the chemistry of the transplutronics (Taylor 1973b).

The Soviet literature is extensive around both actinides and fission products. Much of it comes from the Institute of Biophysics, Ministry of Public Health in Moscow (Yu. I. Moskalev, L. A. Buldakov, E. R. Lyubchanskii, A. P. Nifatov, and colleagues).^(a) Much of the work with plutonium was translated by A. A. Horvath in Albuquerque, New Mexico, edited by R. G. Thomas at the Lovelace Foundation, and published in English under the title "Problems of Plutonium Toxicology" (Buldakov et al. 1970). Many other papers have been made available in the AEC Translation series from DOKLADY BIOPHYSICS.

It is of interest that the tendency for USSR work to dwell heavily upon neurological events, especially at the level of the synapse, seen extensively in their work concerning external radiation effects, is not so prominent in the research on internal emitters. The USSR work does tend to be more diversified, especially in later years, in contrast to what appears at times to be a single-minded obsession with bone tumors in contemporary U.S. work. It does not appear that the USSR work adds qualitatively new information in broad physiopathology to what came out of the MED work. But since the Russian work was done under less pressure than the MED work, it is sometimes more thorough and extensive, especially regarding general physiological effects.

The French laboratory at Fontenay-aux-Roses under the Commissariat à l'Energie Atomique includes much work on alpha emitters, as we saw in the chapter on radon and the uranium miners. J. Lafuma, H. Metivier, and J. C. Nénot are well-known names in internal emitter toxicology. Many other laboratories abroad had active radiobiology programs, but did not delve much into radioisotope toxicology.

VII. The Transplutonic Elements

A. Introductory Considerations

A small amount of work was done with the transplutronics at Berkeley during the war years (see for example, Scott, Axelrod, and Hamilton 1949), but most of the serious investigations were postwar. Americium-241 was added to the Utah beagle experiment in 1966 (^{249}Cf and ^{252}Cf , and ^{243}Cm and ^{244}Cm somewhat later), and there was additional work at Berkeley. On the whole, biomedical work with the transplutonic elements was rather scattered, both geographically and in the literature. Several laboratories were engaged with them, but none were involved in all-consuming efforts such as those we have seen for plutonium and the fission products.^(b) Until Pat Durbin put together her magnificent

(a) We have already noted the extensive work from the USSR with polonium and will see a little of their participation in the worldwide fallout programs in chapter 12.

(b) One reason was the relative scarcity of these substances for many years. Their production and accumulation in power reactors, and the need to handle them in fuel reprocessing and in waste disposal, generated considerable need to know, but availability in pure form for research does not automatically follow a need.

and comprehensive review, already cited (Durbin 1973), anyone trying to find out what had been done biomedically with the elements above plutonium in the periodic table was in for a tedious library search.

In chapter 7, section II, we reviewed the definition of the transplutonics and the wartime biomedical research done primarily at Berkeley. In section II of this chapter, we reviewed Durbin's systematic study of the lanthanides from lanthanum through lutetium, some comparisons of ^{241}Am to ^{45}Ca , of ^{241}Am to ^{239}Pu , and a summary of the review literature from Berkeley. In section III B, we saw the levels of ^{241}Am in the Utah beagle dog experiment (tables 8.5A,B), the retention equations for ^{241}Am and the two californium isotopes (table 8.7), and a few of the early results with californium.^(a) We also caught glimpses of transplutonic element research at Hanford and Los Alamos.

Our purpose here is to draw together a succinct summary of the conclusions of the research worldwide and its significance. First consider the fact that americium and curium (elements 95 and 96) maintain a very stable valence III state, whereas plutonium is stable in valence IV and VI states primarily. Consider also that the transplutonic elements are all radioactive, with shorter half-lives and thus higher specific activities than ^{239}Pu . Most are alpha emitters, although spontaneous fission occurs with some (e.g., ^{252}Cf). In either case, the biological effectiveness is high, especially relative to the lanthanides to which they are chemically analogous.

In a very useful summary table of mammalian studies in the review by Durbin (Durbin 1973, table 18.3), there are over fifty references to work with americium through 1972. Of these, approximately twenty-five were from U.S. laboratories (Berkeley, Hanford, Lovelace, N.Y.U., and Utah), eleven were from the Soviet Union (mostly the Institute of Biophysics in Moscow), eleven were from the United Kingdom (mostly the Institute for Cancer Research in Sutton, Surrey), two were from Lafuma's laboratory in France, and two were from the Nielsen group in Sweden. Of nine references to mammalian research with curium, six were from U.S. laboratories, two from France, and one from the USSR. There were two references to berkelium research, one each from the United States and the United Kingdom, and seven to californium, five from the United States and two from the United Kingdom. The distribution of work was about proportional to the number of references, except that the publications from the USSR were more summary in nature and gave less experimental detail. They alluded, however, to much more work to back up the conclusions given. The animals contributing were rodents, dogs, sheep, pigs, and monkeys.

The information discussed in the rest of this section was coordinated primarily from the Durbin chapter and from testimony on the biological effects of transuranium elements in experimental animals prepared by W. J. Bair for the 1974 EPA Hearings on Plutonium and Other Transuranium Elements (Bair 1974). Information in humans comes almost entirely from a few accidental exposures, particularly to americium, and uses in nuclear medicine (californium). We will take up these human exposures with others in chapter 16.

(a) Although the initial addition of transplutonics to the Utah experiment was a decade and a half ago, only a few dogs could be added at a time because of limitations of kennel space and care. Therefore, the story is only now becoming reasonably complete with more still to come.

B. Behavior in the Body (Metabolism)

The transplutonic actinides are in general more mobile in the body than is plutonium.

1. Absorption

Americium, curium, berkelium, californium, neptunium, and einsteinium are all more readily absorbed from the gastrointestinal tract than is even the most soluble form of ^{239}Pu , the nitrate. Corresponding salts of ^{238}Pu are more readily absorbed than those of ^{239}Pu . Some of the figures are given in table 8.10, taken from Bair (1974). It will be noted that some of the transplutonics are over an order of magnitude more readily absorbed from the intestinal tract than the same salt of ^{239}Pu .

TABLE 8.10. Gastrointestinal Tract Absorption of Transuranics in Rats (percent of administered dose)

Transuranic	Compound	Newborn	Adult
^{233}U	Nitrate	7	0.2
^{237}Np	Nitrate	1	0.9
^{238}Pu	Nitrate	2	0.03
^{239}Pu	Nitrate	0.3	0.003
	Chloride	—	0.007
	Oxide	—	0.0001
^{241}Am	Nitrate	9	0.07
	Chloride	—	0.03
	Oxide	0.5	0.01
^{244}Cm	Nitrate	6	0.2
	Chloride	—	0.05
	Oxide (aged in H_2O)	2	0.1
	Oxide (fresh)	0.3	0.03
^{249}Bk	Chloride	—	0.01
^{252}Cf	Nitrate	4	0.1
^{253}Es	Nitrate	4	0.03
	Chloride	—	0.06

Information in this table was developed from published reports and from results of current research at PNL by M. F. Sullivan.

Source: Reser from Bair 1974.

Durbin (1973) gives "best available estimates" of intestinal absorption (expressed as fractions of the dose) of multicharged cations in this series as:

^{144}Ce (valence III), 0.1% to 0.15%
 Trivalent actinides, 0.01% to 0.06%
 Pu (valence IV), 0.003% to 0.012%

She also gives absorption of actinide III chlorides as about five times as great as $^{239}\text{Pu}(\text{NO}_3)_4$ and from one-tenth to one-half as much as the intestinal absorption of $^{144}\text{CeCl}_3$.

Intramuscular absorption was again considerably ahead of ^{239}Pu (as either chloride or citrate).^(a) They do not show the long half-time component on the order of years seen in the absorption of plutonium from wounds.

Absorption through the intact skin has not been looked at extensively but seems to be of little importance unless the radioelement is in an organic liquid.

After inhalation, the transplutonics also showed behavior that contrasted somewhat with plutonium. There was less tendency for them to aggregate in lung, a phenomenon that we will discuss in chapter 9, and, in general, there was more rapid clearance from the lung to gastrointestinal tract or tissues. The aggregation in pulmonary lymph nodes is less marked than with plutonium.

2. Tissue Distribution

In general, all transuranics (i.e., neptunium, plutonium, and the transplutonics) exhibit similar tissue distributions in the long run. They all eventually settle in bone, as the organ of highest concentration, except for retention of very insoluble compounds in the lung. But in the early phases of absorption, the transplutonics, in general, go to soft tissue in larger quantity than does plutonium. This is especially true of liver, except for einsteinium. However, excretion from liver is fairly rapid too. This accounts in part for the emergence of bone as the organ of highest concentration eventually. Differences caused by chemical form, route of administration, or interspecies variations, may wipe out differences attributable to the element's properties per se, but the generalization holds when these other influences are factored out.

Kidney is frequently an important early deposition site. But urinary excretion may range from an important route of elimination to one of negligible importance for some compounds that are lost almost entirely via biliary excretion from liver to gastrointestinal tract. Cohen and Wrenn (1973), for example, concluded that all of the ^{241}Am deposited in the liver of baboons is excreted via the bile and feces.

Durbin (1973, figure 18.27) has prepared a model containing several compartments to express the metabolism of trivalent actinide elements in mammals. The model contains as major compartments plasma, liver, kidney, bone, incisors (in the rat only), and other soft tissues, with two-way interchange occurring between plasma and liver, bone, and other soft tissues, but only one-way transfer, outward, to kidney and incisors.

An example showing the time course of retention of ^{241}Am in liver, soft tissue, and skeleton is given here in figure 8.18 using Durbin's data from the cynomolgus monkey.

Note first that the points extend over a sufficiently long period to be significant to calculations of internal dose. Note also that the skeletal dose would be high primarily by tenacity of retention. The distribution among compartments is very dependent on the compound involved. Witness, for example, the difference between $^{241}\text{AmCl}_3$ and $^{241}\text{Am}(\text{NO}_3)_3$ illustrated in figure 8.19, taken from some of the Russian work. (Gonadal concentrations of the transplutonic elements appear to be about the same as those of plutonium.)

Cross-placental transfer is small for all the transuranics. However, americium and curium appear to cross the placenta less readily than does plutonium, a curious exception to their generally greater mobility.

(a) Durbin states that citrate complexes of the transplutonium elements are unstable in the body, and their behavior is thus identical to simple salts.

FIGURE 8.18. Retention of ^{241}Am in the skeleton, liver, and residual soft tissues of adult cynomolgus monkeys after intravenous or intramuscular injection of 0.44 to 0.87 $\mu\text{Ci/kg}$ of ^{241}Am citrate. Solid symbols represent pairs of monkeys and open symbols single animals. Data of Durbin, Williams, and Jeung 1972. (Redrawn from Durbin 1973, figure 18.21. Reprinted with permission of Springer-Verlag, Heidelberg, copyright 1973.)

At the microscopic level, the transplutonium elements show both similarities to and differences from plutonium. The ultimate site of deposition in bone appears to be similar for plutonium and, for example, americium: the mineralized bone surface immediately beneath the cellular layers (Durbin 1973, p. 790). On the other hand, one gets the impression that in soft tissues the transplutoniums, being more mobile, are somewhat more likely to appear in diffuse patterns, as contrasted to the polyatomic aggregates characteristic of insoluble plutonium salts. Several laboratories have shown this to be true generally. However, differences in chemical form and route of administration frequently mask differences among the elements. A start was made at Hanford on the metabolism of einsteinium and berkelium (Hungate et al. 1972; Smith 1972). The Utah group (Lloyd et al. 1974) checked out the behavior of curium in the beagle.

The Berkeley and Utah laboratories in this country and D. M. Taylor's laboratory in the United Kingdom have probably made the most extensive and organized autoradiographic studies on the transplutoniums, except for inhaled material, which has been dealt with at Hanford and Lovelace.

FIGURE 8.19. Accumulation of ^{241}Am in the skeleton, liver, and kidneys of rats after intravenous injection of $^{241}\text{AmCl}_3$, (Belyaev 1969) or intraperitoneal injection of $^{241}\text{Am}(\text{NO}_3)_3$ (Tseveleva and Yerokhin 1969). Data are expressed as percent of the maximum uptake in each tissue. (Redrawn from Durbin 1973, figure 18.21. Reprinted with permission of Springer-Verlag, Heidelberg, copyright 1973.)

3. Chemical Binding

D. M. Taylor (1973b) gives an excellent review of the chemical and physical properties of the transplutonium elements of interest in biology. He points out the deficiency of such information relative to plutonium and the problems of avoiding radiation effects in solutions of materials with such high specific activity. Nevertheless, he is able to extrapolate to the group as a whole from work on americium and curium, as well as the actual work on elements of higher atomic weight. He points out their lesser tendency to undergo hydrolytic reactions in solution, the great stability of the III valence state^(a) and, thus, lack of the many oxidation states seen with plutonium. But he emphasizes that complex formation and hydrolysis still play an important part in their solution chemistry. Binding to proteins either in vitro or in vivo seems to be less than with Pu (IV). As a result, these elements may be in several forms in vivo in contrast to the strong complex of plutonium with ferritin.

(a) Nobelium is unique in having valence II as the most stable oxidation state in solution.

Durbin takes the view that the rapid translocation of transplutonic nuclides from soft tissue to blood and then to bone indicates that they are not bound to cellular components, but exist rather in extracellular fluid (ECF). This may be true also in part for Pu (IV), but the stability of the Pu (IV) transferrin complex makes for much slower leakage of plutonium into ECF.^(a)

4. Excretion

Each laboratory has done its share toward furthering our knowledge of the excretion of the transplutonics. But the Berkeley data appear to be the most numerous and most completely studied, except for inhalation work, with Utah and Lovelace close behind. One problem is to be sure the administered levels are low enough to preclude radiation damage. Because of the early deposition in liver, much of the initial excretion is via bile to the gastrointestinal tract. This predicts a preponderance of excretion via the feces, and it is true in general. But contrasts abound. The amount of einsteinium in feces, for example, falls rapidly to about 0.1% of the dose per day at about twenty days, while the amount in urine, which is initially higher than the amount in feces, seems to level off at this same 0.1% per day. By contrast in the rat at least, ²⁴¹Am and ²⁴²Cm start with about 10% of the dose in urine at one day, with a maximum of around 3% in feces at ten days. But the urinary excretion rate falls precipitously to less than 0.02% per day by thirty days, while the fecal excretion rate is almost ten times as high at about 0.3% per day. Berkelium is like einsteinium, insofar as the few data available can tell. These contrasts in early excretion rates are illustrated in figure 8.20A and B (references are to the 1973 paper).

In some cases the feces-to-urine ratio would actually reverse as a function of time. It is unfortunate that the data for urinary excretion do not go beyond thirty-five days, probably because of the difficulties of measuring urine at such low concentrations. On the other hand, in the monkey, where longer-term studies were practical, the excretion of ²⁴¹Am citrate remained predominantly in feces, except in the first few days, out to over fifteen hundred days (Durbin 1973, figure 18.40). With ²³⁹Pu in adult beagles, the ratio feces/urine begins below 1 (about 0.6), goes to about 7 at three days, then gradually falls to a constant value of about 1.5 from thirty to five thousand days (Stover, Atherton, and Keller 1959). It will be remembered that the now classic Langham relations for plutonium excretion in man (chapter 7) put the fecal-to-urine ratio slightly greater than 1 during the first thirty days, while it becomes progressively smaller with time, being less than 1 for the bulk of the period up to at least five years. The difference between man and dog in plutonium excretion is not large, but between man and rat it is very large, with fecal excretion predominating in the rat.

Information of the type gathered is important for those instances where bioassay must depend upon excretion measurements. And the research on balance points to differences between plutonium and the transplutonic elements, with the fecal route more important for the transplutonics. But we have no long-term studies on man with the transplutonics to compare with those on plutonium.^(b) Thus, the generalization must be a cautious one.

(a) In her review, Durbin (figure 18.12) presents a kinetic model for initial transport and deposition of the trivalent elements with compartments for ECF-bound versus free, plasma-bound versus free, liver, bone, excreta, and soft tissues.

(b) The few long-term incidents we have are accidental intakes and were treated with chelating agents (see chapter 19).

FIGURE 8.20A. Early excretion rates of trivalent actinide elements in the urine of the adult rat: ^{241}Am and $^{249-252}\text{Cf}$, Durbin, Jeung, and Williams (1969, 1972a,b); Durbin, Williams, and Jeung (1972); ^{242}Cm , Scott, Axelrod, and Hamilton (1949); ^{249}Bk , Hungate et al. (1972); ^{253}Es , V. H. Smith (1972). (Redrawn from Durbin 1973, p. 837. Reprinted with permission of Springer-Verlag, Heidelberg, copyright 1973.)

FIGURE 8.20B. Early rates of excretion of trivalent actinide elements in the feces of the adult rat. Data sources are the same as given in figure 8.20A. (Redrawn from Durbin 1973, p. 838. Reprinted with permission of Springer-Verlag, Heidelberg, copyright 1973.)

Fortunately, many of the transplutronics can be measured by means other than collection of excreta. Hence, the somewhat insecure footing provided by researches on excretion is not so serious a practical problem as it is a challenge to the understanding of mechanisms. While some work is continuing in this field, it has had to be curtailed by the needs in other areas, including chemical toxicology and environmental transport problems.

5. Addendum: Distribution and Retention

Recently, the group at New York University has published the results of several years of work on the metabolism of ^{243}Am and ^{244}Cm in the baboon (Lo Sasso, Cohen, and Wrenn 1981). In the discussion section, they present an interspecies comparison of americium and curium deposition and retention in liver. This is reproduced below as table 8.11.

It appears that the two elements, americium and curium, behave quite similarly in a given species, but differences among the species are large; the differences do not follow any obvious relationship to body weight. This interspecies problem does not appear to extend to bone.

TABLE 8.11. Interspecies Comparison of Actinide Deposition and Retention in Liver

Species	Route of Exposure	Chemical Form	²⁴³ Cm		²⁴¹ Am	
			Initial Deposition in Liver (% injected dose)	T _{1/2}	Initial Deposition in Liver (% injected dose)	T _{1/2}
Rat ^a	iv	Citrate or chloride	60	9.0 ± 0.3 days	57	7.5 ± 0.5 days
Dog ^b	iv	Citrate	35	~ years	50	~10 years
Baboon ^c	iv	Citrate	20	45 days	27	28 days
Cynomolgus monkey ^a	iv	Citrate	—	—	53	70 days

^a Deposition in liver = $L_{\max}(\%) = L_t + G.I._t + \sum Fe_t$, where L_t = amount of nuclide in liver at time t , $G.I._t$ = amount of nuclide in G.I. tract at time t , $\sum Fe_t$ = cumulative fecal excretion at time t .

^b Deposition in liver determined by combination of total-body and partial-body counting.

^c Deposition in liver determined by combination of total-body counting, cumulative fecal excretion, and liver biopsies.

C. Toxicity

1. Acute Effects

The LD_{50/30} (lethal dose to 50% of the animals in thirty days) for ²⁴¹Am has been given by Zalikin, Moskalev, and Petrovich (1968) as 110 μ Ci/kg for rats. Durbin (1973, table 18.32) summarizes acute toxicity findings from Los Alamos, Chicago, Lovelace, and the Institute of Biophysics in Moscow for the three long-lived actinides. LD₅₀ values at 30, 60, 120 to 150, 250, and 300 to 350 days are quite similar for all three elements. The animals were adult and young rats and the Chinese hamster. Durbin (1973, table 18.33) also brings together the acute toxicity data for the dog using primarily work from Utah, Chicago, Lovelace, and Moscow. The information is sparse on the dog, since few investigators wish to expend valuable dogs in acute toxicity experiments when they might contribute information on long-term metabolism and effects. However, it appears that the same story applies to the transplutoniums as to plutonium: somewhat greater sensitivity in the dog by a factor of about two. The transplutoniums and plutonium are, on balance, not significantly different, at least in the dog.

Thus, the differences in deposition in soft tissues described in earlier paragraphs seem not to affect acute toxicity of the longer-lived transplutoniums compared to plutonium. Einsteinium, being both shorter lived and more rapidly excreted than americium or curium, is less toxic per activity unit (μ Ci) administered. Durbin estimates the LD_{50/30} in the rat as about 250 μ Ci/kg. The lack of difference in acute toxicity of these elements, despite significant differences in tissue distribution, recalls a point made by Stannard many years ago (Stannard

1956): there may be many occasions with elements depositing in several tissues when toxicity is better related to total body burden than to the burden in any single organ.

The effects earlier than sixty days with these large doses are referable primarily to bone marrow injury. Later deaths appeared to be referable to several organs. The most sensitive indicator of damage, as usual, is depression of the white cell count.

On the postulate that distribution of ^{144}Ce - ^{144}Pr is quite similar to that of plutonium, americium, and curium, Durbin used the acute toxicity as a way to compare the effectiveness of alpha emitters with beta emitters deposited in the body. The $\text{LD}_{50/30}$ averaged $100\ \mu\text{Ci/kg}$ for the alpha emitters in rats and was much smaller than the $1,830\ \mu\text{Ci/kg}$ for the beta-emitter pair ^{144}Ce - ^{144}Pr . In the dog, the figures were $35\ \mu\text{Ci/kg}$ versus $110\ \mu\text{Ci/kg}$. The difference between alphas and betas is clearly significant, with the alpha emitters, as always, the more effective. It is not difficult to explain why the ratio of effectiveness is smaller in the dog than in the rat. The range of the beta particles is likely to include much more bone and bone marrow in the dog and be dissipated more outside of bone and marrow in the rat.

Durbin points out that the relative effectiveness for bone marrow damage may be inversely related to body size.

2. Long-Term Effects

a. Bone Tumors

There is no doubt that the transplutronics can produce bone tumors. Indeed, osteogenic sarcomas appear to be the most sensitive effect produced by deposition of plutonium, americium, curium, and einsteinium in mice, rats, and dogs (Bair 1974). The Utah beagle experiment and the Russian work are the prime sources of information concerning parenteral administration to the dog. But the Utah work is even now not far enough along to support calculation of toxicity ratios to radium, which we examined in detail earlier for some other elements. We can only speculate that the relationship will resemble that for plutonium. Information after inhalation (details in chapter 9) comes primarily from PNL, Lovelace, and the USSR.

There is much more information on the rat, but it is not easy to sort out clear-cut evidence on whether or not the transplutronics are more efficient, less efficient, or about the same as plutonium in inducing bone tumors. The earliest postwar study in the rat was done by Langham and Carter (1951) with ^{241}Am . They gave 32 to $63\ \mu\text{Ci/kg}$. Six of thirty-two animals (19%) developed osteogenic sarcomas before 350 days. The associated radiation doses were 7,800 to 16,000 rad, not an indication of high efficiency of the transplutronics. Indeed, the administered dose was quite high, and life spans were short.

Later experiments detailed by Durbin showed similar percentages of bone tumors at much lower administered doses of ^{241}Am , e.g., $2.5\ \mu\text{Ci/kg}$ and $5.8\ \mu\text{Ci/kg}$ and associated radiation doses of 1,800 to 2,500 and 1,700 to 3,100 rad depending upon how long the animal lived.

David Taylor and his colleagues in the United Kingdom (e.g., Taylor and Bensted 1969; Bensted, Taylor, and Sowby 1965) found the rat to be significantly less sensitive to ^{241}Am than to ^{239}Pu in terms of bone-tumor development. The dose levels of ^{241}Am were 2.5 to $7\ \mu\text{Ci/kg}$ and were compared with $3\ \mu\text{Ci/kg}$ of ^{239}Pu , given intravenously. The americium doses produced 21% and 47% bone

tumors, respectively, while the plutonium dose produced an 80% incidence. There were soft-tissue lesions, including leukemia, in all groups of rats, but these did not show the same relation to dose. The authors propose an explanation of the difference between the elements as follows:

1. Plutonium deposits much more heavily on endosteal surfaces than does americium.
2. Plutonium is bound quite strongly by bone sialoprotein. Binding of americium to it is weaker (preliminary observations).

The U.K. workers are fully convinced that americium is less effective than plutonium in producing bone tumors, but suggest going to still lower dosage levels that have less shortening of life span from other causes.

There is probably no real conflict between the U.K. conclusions and those from the Durbin summary. The latter considered a number of disparate experiments from many laboratories. The conclusion that americium is about equally effective as plutonium is probably conservative for the rat, but not for the dog. Obviously, we need not only more long-term information for americium, but much more complete studies for curium and the other transplutronics to be secure quantitatively, or to consider alteration of allowable intake.

b. Other Long-Term Effects

Inhaled actinides can produce lung cancer, but there may be a difference between transplutronics and plutonium. The greater mobility of the transplutronics may result in shorter residence time in lung and more deposition in skeleton. We will examine this question in chapter 9.

Bair (1974) proposes from studies in rats that ^{253}Es is less efficient than plutonium in producing lung cancer, but more efficient in producing bone cancer. The information was obtained from animals receiving the einsteinium by intratracheal instillation.

A very interesting finding in the dog is concentration of americium in the thyroid. This came largely from Utah work. G. Taylor et al. in a Utah annual report (Taylor et al. 1976) describe morphological changes in the thyroid in young beagles receiving 2.88, 0.91, or 0.296 $\mu\text{Ci/kg}$ of ^{241}Am . The percent of injected dose per kilogram of thyroid tissue varied from about 20 to over 100,^(a) higher than skeleton and only a little lower than liver (Lloyd et al. 1967; Atherton et al. 1968).

No symptoms of clinical thyroid deficiency have appeared even yet, but microscopic lesions such as fibrosis, loss of colloid, loss of follicular and increase of residual epithelium have all occurred. While no thyroid tumors have appeared, it is not unlikely that one or more will turn up if bone tumors do not interfere first.

Liver and kidney failure have been reported in the dogs. The occasionally noted tendency of americium to be lethal sooner than ^{239}Pu may be linked to such effects.

The usual radiation effects are seen on the components of circulating blood. All of the transplutronics are more effective than ^{226}Ra , with a curious special effectiveness of californium in reducing the leucocyte count. There has been considerable effort in the area of cytogenetic changes in the cells of liver and

(a) The weight of the thyroid in the beagle is, of course, never as much as a kilogram. Hence, depositions of over 100% on a kilogram basis are understandable.

bone marrow. These are summarized in Durbin's review. The work has continued, especially at Lovelace and in the USSR. While it is hard to equate frequency of chromosome aberrations to other manifestations of biological effect, intercomparisons for this effect are instructive. For example, the beta-emitter pair ^{144}Ce - ^{144}Pr produced about one-twentieth the effect produced by ^{241}Am or ^{252}Cf with no dose-rate dependence for the alpha emitters.

The aberration frequency for ^{252}Cf was lower on the basis of accumulated radiation dose than that for ^{241}Am , despite the fact that about 3% of the nuclear transformations of ^{252}Cf are spontaneous fission reactions. If the energy is calculated for the particles alone, then ^{241}Am and ^{252}Cf are about the same (Durbin review). The investigators (Brooks, McClellan, and McKay 1971; Brooks, Mewhinney, and McClellan 1972; and McKay, Brooks, and McClellan 1969) speculated that the fission fragments might have too short a range in the tissue to be scored in their system, or much of their energy was wasted because of their very high LET. But this finding should not be extrapolated to other effects of ^{252}Cf .

Effects of the transplutronics on growth and reproduction have been studied, especially at PNL and in the USSR. Again americium was the element most used. There seemed to be a threshold dose (less than $4\ \mu\text{Ci/kg}$) in the pregnant female below which implantations were normal, and rapidly increasing numbers of embryonic and intrauterine deaths occurred as the dose was increased. Apparently enough of these elements can pass the placenta to exert effects, even though, as we saw earlier, they do not cross easily.

Alterations in postnatal development of the offspring of ^{241}Am -injected female rats included slow development, depressed reproductive capacity, and some blood disorders.

3. Effective Toxicity

Toxic effects per se are not the only factor controlling the risk of a given element. As we shall see in chapters 15 and 16, metabolic behavior in the body and transfer in the environment may modify inherent toxicity. We can call the result "effective toxicity."

Stannard (1975b) compared the effective toxicity of the transuranics by calculating ratios of their maximum permissible concentrations to that of tritium. With oral intake, iodine and strontium are well ahead of uranium, ^{239}Pu or ^{241}Pu , and ^{247}Cm ; ^{233}U and ^{247}Cm are ahead of ^{239}Pu ; while ^{241}Am and ^{239}Pu are about the same. By contrast, the maximum allowable concentrations in air give plutonium the highest ratio against tritium (3.3×10^6). Americium is a factor of ten less. Both of these were with bone considered as critical organ. The ratio of plutonium to tritium is somewhat less when lung is the critical organ, but still very large (2×10^5).

4. Comment

It is important that current long-term toxicity studies with the transplutronics be carried to completion. There are still gaps in the picture—especially for the elements above americium. But it is also important that the pharmacodynamics in humans be understood well for the development of good metabolic models. We will look at these activities further in chapter 16.

VIII. Summary and Commentary

The three decades after World War II saw enormous efforts embracing the health aspects of radioactive materials. Much of it concerned their uses in diagnosis and therapy (see chapter 20), some of it concerned efforts at therapeutic removal of deposited radionuclides (see chapter 19). Much of the remainder focused on the untoward effects we had perforce to concentrate on in reviewing the wartime work. Some of the largest and longest experiments in the history of biomedicine were organized around extensions of the problems perceived in the 1940s. These included in-depth comparisons of the metabolism and effects of important radionuclides in "king-sized" experiments with beagles; multi-generational studies in sheep and swine; a modicum of work on primates; and an enormous investment of time, talent, and resources in definitive inhalation experiments. (The inhalation work is described separately in chapters 9 and 10.)

Although no large populations of humans were exposed, except to the fallout from weapons tests (chapter 12), there were a few metabolism experiments on patients in metabolic wards, and rather intensive study of a Los Alamos worker population that had been in areas of relatively high potential contamination during the war years. In addition, the workers at the Rocky Flats plutonium plant received special scrutiny along with the environment around the plant. No biological effects have yet been discovered in any of these populations that could be attributed clearly to exposure to plutonium or other actinides. This is rather remarkable when the opportunities for intake are considered. As Dr. Louis Hempelmann, who had much to do with the medical care of the Los Alamos workers, remarked, we can be thankful indeed that plutonium is much less soluble in the gut and less transportable than radium. Except for that, we might easily be now studying a population of exposed individuals with health effects comparable to those from radium.

The chapter begins with a review of postwar work at Argonne National Laboratory and the University of California at Berkeley. This added considerably to their wartime efforts. At Argonne, the largest effort involved completion of the relative toxicity comparisons in the mouse, considerable expansion of the characterization of pathology, and forays into possible cofactor mechanisms for carcinogenesis.

Next is a discussion of the systematic studies at Berkeley, doing what Dr. Patricia Durbin characterized as "chewing our way through the periodic table." Primary emphasis was on strontium, cesium, various lanthanons, and heavy metals. Also, the potential for astatine to supplement iodine in treatment of thyroid disorders was explored until it was clear that it offered no advantages. After the death of Joseph Hamilton, much of this work was carried forward by Dr. Durbin.

The development of the king-sized experiments at the University of Utah, the University of California at Davis, and the Lovelace Inhalation Toxicology Laboratory is traced in considerable detail. Results of the Utah work are examined, while those of the Davis and Lovelace projects are postponed for more appropriate later chapters. These major experiments, now approaching conclusion (1987) of their original objectives, added immeasurably to our knowledge of metabolism, effects, and mechanisms of action of the selected fission products and actinides. Yet, there is still work to be done, especially to follow up cues toward cancer mechanisms developed in the studies.

The postwar years at Hanford (PNL) saw a major study of iodine in sheep, of strontium in miniature swine and in pygmy goats (more in chapter 13), of

radionuclides in the juvenile and fetal mammal, of gastrointestinal tract absorption and effects, and some of the earliest definitive research on the behavior and effects of tritium in biological systems. Much of this is summarized in the many Hanford symposia, whose titles and references are given. Perhaps the greatest surprise was the lack of effect on reproductive performance or on the fetus of significant body burdens carried over several generations. Only when the mother's health deteriorated significantly were there clear effects in these areas.

Los Alamos was able to mount bona fide research with various fission products, the actinides, and tritium after being inhibited during the war years. This was in addition to the careful study of the Los Alamos worker group, the general population of Los Alamos, and the "hot particle" problem (see chapter 9). Among the key results of the Los Alamos work was a long series of reports by Chester Richmond and his colleagues on the comparative metabolism of radionuclides in mammals. As we will see in later chapters, Wright Langham, who brought infinite patience to the characterization of plutonium excretion in humans and animals, was identified with all aspects of plutonium biology to the extent that he was frequently regarded as "Mr. Plutonium" in postwar biomedical circles.

Work from many other quarters is added, including some of the work done abroad.

Since studies of the transplutonic elements were not concentrated in any single major experiment, the postwar work with these is drawn together as a separate section of the chapter. Here, the indefatigable efforts of Patricia Durbin in bringing together a scattered and disparate literature are especially evident. It appears that many of the transplutonics (e.g., americium) are more transportable than is plutonium, and may be even more effective. However, the returns are not yet in on this feature.

The appellation "Golden Era" may be quite appropriate for these major undertakings, especially when taken together with the inhalation work to be described presently.

Note added in proof: An important review of the several long-term dog experiments discussed in part in this chapter occurred at the twenty-second Hanford Life Sciences Symposium. This and a still more recent review by Thompson of the legacy of the experiments have been added to the summary of our knowledge in chapter 21.

**NOTE 1—Text of Statement by Dr. Walter Claus (AEC-ERDA)
at the Twenty-Fifth-Anniversary Symposium of the Utah Project**

One may well wonder, philosophically, what has been the chain of events that lie behind us—how we, you and you and I—happen to be here together tonight. I recently came into possession of an ancient scroll that seems so pertinent to this occasion that I would like to read to you a few of its passages on Genesis, for therein it is written:

In the beginning, there was only ignorance and darkness, broken but by the faint gleam of radium in Bob Evans' bone-pile, while in a fabled land far to the East there did exist, for one brief shining moment, a fleeting wisp of glory known as AEC/DBM. And there, upon a throne of gold sat the Great White Father, and the light from him did shine as the sun cast from a

thousand polished shields—and his name was Warren. And the Father turned to his noblest son, Bowers, who sat upon his right hand, and he said: "Go thou hence, John, and bring light unto the benighted." And John did, and he called upon his henchmen, Evans, and Brues, and Eisenbud, and Brandt, and Claus, and together with the Great White Father, they gathered in that big hostelry beneath the sign of the bee-hive, and enunciated the Dogma, that "as radium in man shall be unto radium in the dog, so shall plutonium in man be as plutonium in the dog." And the statistician proclaimed that the number of the dogs shall be as thirty in each group, and all proclaimed that the name of the dog shall be Beagle. Now these mighty words were hailed abroad as one giant leap for mankind—but they were a very small step for the Beagle.

And so there came to be, in this land of the bee-hive, a great colony of Beagles, and of men and women to succor them and to administer to their wants—Red Stover and Betsy Stover (Adam and Eve in this new world), Bob Bay, Marv Van Dilla, Jim Arnold, Webster Jee, Dave Atherton, Jean Dougherty and Garth Westenskow—and over all did Bowers, the Noblest, in his wisdom and benevolence, brood upon them.

And then again, in that mystic land far to the East, the Father turned to his tiniest son who sat far down upon his left hand, and he spake thus: "Go thou, Walter, and cause to fall upon our chosen ones a deluge of golden manna, but be not overly generous lest they desert the Dogma for the pursuit of ikons and glittering gadgets." And Walter did; and he caused his golden lyre to sing of the beauties of thrift and economy to Stover, the Red—but that young devil took the lyre and all!

And lo! the Colony took unto itself the name "Radiobiology Laboratory," and it thrived. But in that great land to the East, the father-figure of Warren became that of Bugher, and Bugher became Dunham, and Dunham became Totter, and Totter became Liverman; while the stewardship of Claus became that of Bruner, which became that of Carter and Wachholz. The AEC became ERDA, and DBM became DBER. In the Colony, the moving spirit of Bowers became that of Dougherty, and that of Dougherty became that of Jee; while only the Master-mind of Evans goes on, and on, and on!

But still the Colony thrived, even unto its twenty-fifth year, and it sent forth many emissaries into the Land of Science, and it produced myriads of learned facts and fancies, speeches and books, and publications in the journals of the world, and symposia and conferences and workshops—and wise men and women gathered there to give homage in the jargon of science and technology.

So end the passages in my scroll, and thus we see how it comes to pass that we are gathered here tonight—you and you and I.

Amen. (Claus 1976)

Preface to Section III Inhalation Toxicology

Primary concern for health effects of radionuclides centered, until very recently, on their potential inhalation in the work place. In the early decades of the twentieth century, occupational exposures in the "dusty trades" had left a dismal trail of death and incapacitation due to effects of the inhaled dust on the respiratory system. A respectable start had been made toward measurement and control by the new specialty called industrial hygiene. Also, a modicum of research with animals inhaling chemicals of various degrees of toxicity had developed during the late 1920s and the 1930s.

The handling of uranium ore as one of the earliest major jobs of the new atomic energy industry proved also to be a dusty operation. The perceived health problem was again inhalation. Hence, a major effort was devoted to the inhalation toxicology of natural uranium. We have already seen one such experiment in chapter 2. There was much more, as we shall see presently.

It was a relatively small jump from inhalation experiments with chemically toxic substances to a low-specific-activity radionuclide mixture such as natural uranium. The basic apparatus and the control procedures could be developed without undue concern for contamination of the laboratory or operating personnel. Study of the more highly radioactive substances, whether natural or manmade, posed quite different problems. The prospect of purposely producing an aerosol of moderate to high radioactivity thoroughly frightened both administrators and potential investigators. Yet, as the work of World War II progressed, the need to know at least the behavior on inhalation, if not the effects, of the new radionuclides became more and more strident. It was not even known whether or not the presence of radioactivity would so change the charge characteristics of inhaled aerosols that information on distribution and excretion gained with stable isotopes would be inapplicable. Nor was there any good information on how to classify the lung and its accessory structures with regard to their radiosensitivity.

Therefore, during World War II, in addition to the inhalation work with uranium and thorium, there were a few forays into exposures to airborne polonium, plutonium, and the fission products. Obviously, dust feeds and the usual techniques for radioactively inert substances would not do. Instead, small experiments were designed in which the radioelement was volatilized from a hot wire or other small-scale devices. These provided some information on metabolic

behavior of inhaled radionuclides and confirmed the suspicion that there could be no surrogate for actual inhalation exposures. However, they gave no information on biological effects—especially the nagging problems of lung cancer. Such was urgently needed.

Fortunately, the almost absolute containment of radioelements within the “dry boxes” used for machining of uranium and plutonium, developed during World War II, encouraged early postwar investigators to apply the technique to experiments with aerosols of radionuclides. Also, much had been learned about aerosols and how to handle them and of the effect of particle size on retention and subsequent behavior. The work was expensive and laborious since all active systems needed to be at reduced pressure, and very efficient filter systems needed to be interposed at the final outlet. Also, the services of an aerosol physicist were essential for a successful program. As a result, there could not be very many laboratories engaged in such work. There developed a few major centers that specialized in the biomedical work with radioactive aerosols.

The chapters in this section describe the work during World War II and then the development of and results from the major centers that sprang up after the war and are, with one exception, still extremely active. The results have confirmed many times over the need for an actual inhalation experiment. Plutonium, for example, proved to be a potent producer of lung cancer on inhalation, despite the fact that the work described in section II, chapters 7 and 8, linked it primarily to bone cancer.

It must be concluded that because of the interest and dedication of the workers concerned and the continued support of federal agencies, the inhalation toxicology of radioactive materials has led the way for all of inhalation toxicology. It is hoped that these chapters illustrate the concepts, the techniques, and the principal results.

For convenience, work with substances that behave primarily as particles has been gathered in chapter 9. Substances that behave primarily as gases are discussed together in chapter 10.

The theoretical cutoff date (1980) for comprehensive inclusion of material in this book was advanced somewhat for these chapters because of the vigorous activity in the field. Nevertheless, only work of special importance or concern done in the early 1980s could be included in this already lengthy discussion.

Capsule Chronology

- 1920s and 1930s** Work on toxic gases in laboratories of physiology, pharmacology, and toxicology, public health, industrial medicine, and mine safety on both sides of the Atlantic.
- 1930s–early 1940s** Development of aerosol science, advanced especially by invention of the electron microscope.
- 1940** Warren and Gates. Radiation pneumonitis described.

PERIOD OF WORLD WAR II

- 1943** Model experiment at Berkeley on airborne fission products (Hamilton and W. Cohn).
Preliminary investigation of airborne products from Chicago cyclotron (E. Tomkins).
- 1943–1947** Inhalation experiments with natural uranium at Rochester. Extensive studies on three-shift-a-day basis. Many species, compounds, acute, subacute, and chronic levels of exposure. Much correlative work on aerosols, design of exposure chambers, role of particle size. Reported primarily in National Nuclear Energy Series volumes in 1949 and 1951 (Voegtlin and Hodge).
- 1944** Metabolism and effects of short-lived airborne fission products using the Clinton "Pile" (Lanz and Teresi at Chicago). Work begins at Berkeley on aerosolized products of uranium bombardment at cyclotron (Hamilton and Scott).
- 1944–1945** Animals exposed to off-gases from Clinton "pile," mostly fission products (Scott et al. at Berkeley).
Chamber exposures with arcs and sparks, as well as sprays. Fission products and plutonium. Work at Berkeley (Scott et al.).
Extensive autoradiographic work with both the aerosols themselves and the animal recipients. Clear that insoluble complexes form in the lung and that inhalation picture is not the same as after intratracheal instillation (Berkeley). Some of the work not written up until after the war.
- 1944–1946** Work by Abrams at Chicago (Met Lab). Consistent efforts to develop aerosol technology. Methods devised for a wide variety of radionuclides. Both metabolism and effects studied. Larger quantities used than at Berkeley.
- 1944–1947** Inhalation work with rats at Rochester using ^{210}Po (Kimball and Fink). Aerosols administered by burning wire technique or nasal cannulation. Distribution different from after intravenous administration. Published in NNEs^(a) volume in 1950 (Fink).
- 1945** Acute toxicity of inhaled ^{144}Ce , also ruthenium (Abrams at Chicago). Tracer work begins on inhaled plutonium. Noted that it remains in lung for long periods (Abrams at Chicago).

(a) For abbreviations and acronyms, see Appendix D.

- 1946 Major summaries of Chicago work on inhalation of longer-lived fission products, also intubated and inhaled plutonium in rats (Abrams et al.).
High effectiveness of plutonium in producing lung damage hinted at by intubation work.
- 1948 Bloom reports on histopathological effects of inhaled radionuclides. Work done during the war (Chicago).

POST-WORLD WAR II

- 1949 First two volumes of Rochester uranium work published.
- 1949 et seq. Expansion of work on relation of particle size to toxicity, mostly at Rochester.
- 1949–1952 Follow-up at Berkeley of autoradiographic work done during war.
- 1950 Rochester experiments with inhaled polonium published.
Aerosol science becomes a separate entity at some projects.
- Early 1950 Studies at Hanford begin using intratracheal intubation.
- 1950s Inhalation work, mostly fission products and radon, at Naval Radiological Defense Laboratory (Cohn, Gong, and colleagues).
HASL, then NYU, work on inhalation problems in industry, mostly uranium (Eisenbud and Harley).
Studies by Herman Cember at University of Pittsburgh. Mostly insufflation and implanted radioactive beads. In 1960, Cember moves to Kettering Laboratory in Cincinnati and continues inhalation work.
- Mid-1950s Inhalation work begins in earnest at Hanford (Bair and colleagues).
- 1951 Second two volumes of Rochester uranium work published—emphasis on chronic effects. AEC Air Cleaning Conferences begin, continue through 1980.
- 1952 Radioactive Inhalation Section (Alpha Laboratory) organized at Rochester. Broad studies of retention, distribution, and, later, effects. Polonium-210, plutonium, radon, and daughters (see chapter 3) (Berke, L. Casarett, Mercer, Morken, Morrow, Scott, Smith, Stannard, Thomas, and Wilson).
Marinelli studies transport of radium in lung of man (ANL, Chicago).
- 1955 Lung cancer reported at Hanford from instilled plutonium (Wager).
- 1955 et seq. Long-term inhalation experiment with uranium at Rochester (Leach, Hodge, et al.).
NYU work on deposition and clearance of radioactive dust (Albert, Lippmann, and Laskin).
- 1955–1964 Polonium exposure of dogs and rats at Rochester.
- 1957 Lung cancer produced in rat by ^{210}Po (Rochester).
- 1958 Plutonium inhalation exposures begin at Rochester.
Malignant lung tumors appear in animals at Hanford receiving ruthenium dioxide by inhalation (Bair, Willard, et al.).
NYU work on implanted sources in lung.

- 1958-1961** Iodine inhalation work at Hanford (Bair and Willard).
Reports from Oak Ridge on inhalation of uranium aerosols by animals and man.
- 1959** Aerosol deposition studied in humans using sodium chloride (Morrow, et al. at Rochester).
- 1960s-1970s** Inhalation work at Hanford/Pacific Northwest Laboratory begins to concentrate on plutonium and radon + daughters. Long-term effectiveness of plutonium in producing lung cancer made clear (Bair, Park, et al.).
- 1960-1964** Lovelace Foundation Fission Product Inhalation Laboratory organized and facilities built (later called Inhalation Toxicology Research Institute). Early exposures limited to small animals. First dog exposed in 1964. Cesium-137 used. Soon followed by ^{91}Y , ^{144}Ce , and ^{90}Sr , all in both soluble and insoluble forms. Idea of using fused aluminosilicate particles as carriers for insoluble aerosols developed (White, Mercer, Thomas, Lie; later McClellan, Boecker, et al.).
- 1960-1964** Definitive reviews from Rochester on deposition and clearance mechanisms (Morrow and Casarett).
- 1960s through 1970s** Inhalation program at Wayne State University. Mixtures of stable and radioactive aerosols, rare earth elements (Vorwald and Berke).
- 1964** Air pollution by radioactive materials from fossil fuel plants described (Eisenbud, NYU).
SNAP-9 enters the atmosphere with 17 kilocuries of ^{238}Pu released. Much work and discussion of possible inhalation hazards from such sources.
Hanford biology symposium on Inhaled Radioactive Particles and Gases (Bair et al.).
Inhalation problems enunciated and studied in depth around projects such as SNAP, ROVER, Kiwi, and NERVA.^(a)
- Mid-1960s** Oak Ridge cooperative program with National Cancer Institute. Effect of external radiation on clearance and behavior of inhaled stable aerosols.
- 1965** Lovelace directed to place primary emphasis on the dog and include longevity studies.
- 1966** ICRP Task Group Lung Model published (Morrow et al.).
- Late 1960s** Sanders's work begins on peritoneal macrophage and plutonium. Expanded to pulmonary macrophage in subsequent years (Battelle).
- 1970** Differences in metabolism and effects between ^{238}Pu and ^{239}Pu established clearly (Stuart, Bair, et al., Battelle).
Relationship worked out between inhaled dose of plutonium and long-term incidence of lung cancer (Bair, Thompson, et al., Battelle).
- 1970s** Comparison of single and repeated inhalation exposures at Lovelace indicates real differences (Boecker).
Much lung modeling everywhere.

(a) See text for definitions.

- 1970s Use of whole-body counting begins for study of pulmonary deposition and kinetics in man and animals (Rundo, ANL; Cohn, BNL; and others).
- 1970–1974 Harvard work on polonium (see chapter 4).
- 1971 Monodisperse aerosols developed in usable quantities at Lovelace and used extensively as exposure modality:
Gates and Warren. Reports on lung pathology from implanted sources (Harvard).
- 1972 Lovelace begins exposures to transuranium elements.
- 1973 et seq. Inhalation work with transplutronics reported from Battelle (Ballou, Sanders, et al.).
- 1974 The “hot particle” controversy is launched (Gofman, Tamplin, and Cochran). Several laboratories begin programs in response, several blue-ribbon committees appointed to investigate. Plan developed that Battelle would use polydisperse aerosols, Lovelace primarily monodisperse aerosols, and Los Alamos to use microspheres.
- 1974 et seq. Los Alamos work on insoluble particles, particularly microspheres, as surrogate for “hot particle.”
- 1974–1975 Reports on “hot particle” problem (spatial distribution of dose) as follows:
WASH-1320, The LMFBR report (Bair, Richmond, and Wachholz)
Biophysical Society
Review by Los Alamos staff (Healy, Richmond, and Anderson)
U.K. report (Dolphin)
NCRP report
NAS–NRC report
- 1975 Long-term studies with rodents at Battelle (Sanders et al.).
- 1975–1978 Harvard work in response to “hot particle” issue (Little et al.).
- 1979 Inhalation work with thorium-cycle nuclides reported from Battelle (Ballou et al.).
- 1980 Interaction of plutonium and cigarette smoke added to Battelle reports on interrelationships (Filipy et al.).
ICRP Publication 31, *Biological Effects of Inhaled Radionuclides* released (Bair et al.).

Chapter 9

Inhalation Toxicology—A Special Entity

Radioactive Dusts and Particles

Overview

The most likely route of intake of radioactive materials in occupational exposure is by inhalation. This is true too, but to a lesser degree, for population exposure. An enormous input of manpower, resources, and ideas was showered upon research concerning the inhalation toxicology of radioisotopes both during and after World War II. As a result, the inhalation work in the atomic energy field became preeminent and led the way for all of inhalation toxicology. It still does.

This rather lengthy chapter reviews the research with dust and particles in contradistinction to materials that are inhaled as gases, the subject of chapter 10. The bulk of exposures are to dusts and particles. The research ties closely to fundamental work with aerosols and thus to general problems of meteorology and air pollution, but these are not stressed except where there is a direct bearing on the biomedical problems or instrumentation therefor. With the ascendancy of lung cancer as a cause of death over the last several decades, and the demonstrated ability of radioactive materials to cause cancer, much of the chapter concerns lung cancer from both qualitative and quantitative points of view.

The chapter begins with a review of the rather considerable wartime efforts with radioactive dust at Berkeley, Chicago, and Rochester. It includes work, particularly at Chicago, that languished in various in-house reports and that has not been generally available in published form.

Turning to the postwar years, the chapter considers briefly continuation of work begun during the Manhattan Project days. There follows a short review of developments in aerosol science and consideration of inhalation work done at the Naval Radiological Defense Laboratory. It then launches into the development of and the work at the large centers for pulmonary radiotoxicology: Pacific Northwest Laboratory (PNL) at Hanford, the Lovelace Foundation—Inhalation Toxicology Research Institute, and the University of Rochester. Following these, we consider the important work done at other laboratories that was not on the grand scale of the major centers but was significant nevertheless: Harvard University; The Health and Safety Laboratory—Environmental Measurements Laboratory of the Atomic Energy Commission (AEC), Energy

Research and Development Administration (ERDA), and Department of Energy (DOE); the Los Alamos Scientific Laboratory; New York University Institute of Industrial (Environmental) Medicine; Oak Ridge National Laboratory; Universities of Pittsburgh and Cincinnati; Wayne State University; and miscellaneous others. There are some short comments on work abroad.

The final section of the chapter considers some special activities that acted as focal points for intensive studies, e.g., the "hot particle" problem, tobacco smoke, and some special U.S. government projects for uses of nuclear materials that might involve inhalation hazards. It concludes with brief comments on the role of the Headquarters offices in nurturing and guiding the entire enterprise.

When we remember that initially the very idea of purposely putting up clouds of radioactive materials in the laboratory filled all concerned with apprehension, it is most satisfying to realize that hundreds of experiments have been done without a serious contamination incident or personnel exposure. The engineering, operational protocols, and smooth functioning of the large groups concerned could only have occurred with major and far-sighted commitment of the federal government. No single industry or institution could have mounted such a program.

The results have confirmed all of the early suspicions regarding the possibilities for developing lung cancer (as well as other cancers) from the inhalation of radioactive dusts and particles. They have allowed a start on quantitation of risk. They have shown that the risk can be controlled. They have demonstrated repeatedly that there can be no substitute for the actual inhalation experiment. And, finally, the convenience of a radioactive tag has contributed much to the understanding of basic respiratory physiology and pharmacology and to basic aerosol science. Nevertheless, the work also demonstrates the great reluctance with which nature gives up her secrets. Many important questions remain unanswered, and the quest must continue, especially in the centers already in place, which are developing new knowledge each day.

1. Introduction

As stated earlier (see overview), the most likely and generally the most hazardous route of intake of toxic materials is by inhalation. This has been, and still is, especially true of occupational exposure. The generalization extends back to the early days of industrial hygiene; in fact to very broad areas.^(a) Special methods are needed for collecting samples and analyzing exposures. Appreciation of the complexity of the problems of evaluation began with the clinical problems of coal miners, of silicosis in hard-rock miners, and workers in

(a) An excerpt from the brochure describing the ten-year old *Journal of Aerosol Science* (Pergamon Press) provides this broad picture: "Aerosol particles suspended in the atmosphere influence life in many ways: airborne infection, treatment of disease, exposure to dust at work, safety of nuclear reactors and α -radiation safety, climatic and local weather effects, air pollution, tobacco smoke, pest control, chemical warfare—almost all the enormous sums of money spent on research and development in the field go in these directions.

Underlying every applied problem in aerosols is a complex of scientific knowledge which has been built up over the last hundred years; little systematic education in aerosol science is available, but the *Journal of Aerosol Science* is concerned with this."

the dusty trades above ground. However, despite progress in evaluating and controlling occupational exposures, a relatively small segment of the effort was devoted to controlled exposures of experimental animals. One reason for this was the problem of producing reliably and repetitively an aerosol of known characteristics. Much early experimental work was done by simply using aliquots of the exposure atmosphere or placing animals in the workplace.

In the 1930s and even into the 1940s, experimental work in the United States involving inhalation exposures (in contrast to the fundamental behavior of particles) took place in physiology and pharmacology laboratories interested in asphyxiants and some of the more violently toxic gases; in a few enlightened industrial medical departments around the problems of volatile organic solvents; and, for exposure to particles, in laboratories like the Bureau of Mines, the U.S. Public Health Service Division of Industrial Hygiene, and special university laboratories such as the Kettering Laboratory in Cincinnati. Even a perfunctory review of these enterprises is impossible here, except to recommend that the reader consult the general industrial hygiene literature of the day, and find the series of monographs from the U.S. Public Health Service on silicosis and later from the National Institute^(a) of Health under the editorship of L. Fairhall on the toxicology of a large number of inorganic substances, and the miscellaneous publications from the Bureau of Mines.

The primary reason for the relative paucity of experimental work (as compared to clinical evaluations) was the complexity of aerosol science^(b) and the difficulty of doing experimentally what theory indicated needed to be done. However, under the combined impetus of advances in meteorological science, the urgent problems of the chemical warfare services (at Porton in the United Kingdom and at Edgewood Arsenal in the United States), and particularly the development of the electron microscope, aerosol science leaped forward dramatically in the late 1930s and early 1940s. Here, too, space interdicts any detailed formal discussion, except in connection with the specific problems surrounding radioactivity, which we shall take up in due course. Let it be said, however, that the developments were very much a two-way street. Just as the progress of general aerosol science made possible the study of radioactive aerosols, so did the convenience of measuring small amounts of radioactivity contribute to the understanding of aerosol behavior.

We have termed inhalation toxicology "a special entity" and chosen to discuss it separately, even though the eventual toxic effect of a material once absorbed from the lung may be similar to that of the same substance introduced by other routes. This is partly because of the unique methodologies involved and the development of specialists in the field, partly because of the special problems involved in effects on the lung. For convenience, in this chapter we will consider the most common types of exposure modalities: dusts, mists, smokes, and other situations where particulate material, either liquid or solid, is suspended in air; situations where the exposure modality is a gas, or behaves like a gas, will be deferred to chapter 10.

(a) It was one institute in those days. The experimental work was done in the Division of Industrial Hygiene; field and industry-oriented work was under the Bureau of State Services.

(b) General definitions can be found in the industrial hygiene literature and will not be repeated here. "Aerosol" refers to any suspension of material, solid or liquid, in air, just as "hydrosol" refers to a suspension in water. Stable aerosols are always of relatively small particle size.

II. The Manhattan Project Days^(a)

A. The Earliest Concerns

It did not take long for those concerned with potential health hazards from the radioactive materials about to be handled or produced in the Manhattan Project operations to realize that the inhalation route might be of even greater significance with radioactive materials than in more conventional situations. One of the earliest reports, done in 1942, contained a calculation by Failla on "Tolerance Concentration of Radioactive Gases in Air" (Failla 1942). This bore primarily on energy absorption in various portions of the lung. Each laboratory developed, for its operations, methods and standards for evaluating airborne radioactivity, as seen in the monthly and special reports of the Manhattan Engineer District (MED), copies of which the author obtained from several sources. Examples are the report prepared by Koval (1945) at the Clinton Laboratories and the detailed review of Clinton Laboratory procedures for air monitoring by Parker (1946). Similar documents can be found for Hanford operations.

Very early there was much concern for the hazard from radioxenon contained in the off-gases from the early "piles." The first experimental animal inhalation exposures under MED auspices were around the problem of radioxenon. This was set up at "Site X" (Clinton Laboratories) after calculations of the probable amount of activity to be expected and preliminary experiments.

One of the earlier monthly reports from the Metallurgical Laboratory tells that Waldo Cohn, who is now identified primarily with Oak Ridge,^(b) visited Dr. Hamilton's laboratory at Berkeley to assist in a model experiment on gaseous fission products. The same report describes similar preliminary experiments on radioactive gases produced in the Chicago cyclotron. This was carried out by E. R. Tomkins, whose later work went in quite different directions.

The major internal emitter toxicology programs were at the two Metallurgical Laboratory "branches," Berkeley and Chicago, which we reviewed in chapters 6 and 7. They added inhalation experiments where and when feasible. A surprising amount of information was developed despite the rather crude techniques. Beginning slightly later, (work begun in 1943 and reports appeared soon thereafter), the University of Rochester Project undertook major efforts in inhalation toxicology and gradually became identified as a major center for this type of work. We saw some of it in the chapter on uranium (chapter 2) but must add more details in this chapter.

B. Inhalation Work at Berkeley Under the Manhattan Project

The work at Berkeley appears to have been done in two distinct phases. The first concerned inhalation of gaseous mixed fission products. The second utilized either individual radioisotopes in the later times when carrier-free materials were available as described in chapter 6, or aged mixed fission products with or without the parent uranium or plutonium. In addition, the behavior of plutonium in various forms was examined.

(a) Officially the period of work under the Manhattan District Corps of Engineers.

(b) Dr. Cohn was among the first to formalize internal dose calculations, including inhalation. See reproduction of one of his early postwar declassified papers (1948) in the silver anniversary volume of *Health Physics* (Cohn 1980).

The work on mixed fission products paralleled, to a degree, the broad program at Berkeley on the behavior of unseparated fission products given to animals orally and by intraperitoneal and intramuscular injections. However, the apparatus needed was much more complex in order to catch the products in their initial gaseous state.

To get a start, uranium metal was subjected to deuteron bombardment at the Berkeley cyclotron, and the aerosolized products were inhaled by rats. This was before the pile was in operation. (See "Emanation Experiments" in Hamilton's monthly report for February 1944.) A picture of the apparatus used for this exposure is shown as figure 9.1.

FIGURE 9.1. Equipment for "Emanation Experiment" at Berkeley. The equipment for preparing the aerosol is essentially within the cyclotron (background) and separate from the animal exposure unit. (Photo courtesy of Dr. Patricia Durbin; report by Hamilton 1944, and Hamilton and Scott 1944.)

Later, some of the work was done right at the "pile" (reactor) at the Clinton Laboratories after it came into operation. Here the radionuclides at the very head end of the fission product chain were primarily involved. Since many of these are normally gaseous, they could be brought into the exposure system as gases, but would very promptly decay to their short-lived, normally solid degradation products. Since elimination from the body was rapid, only a small part of these exposures involved the longer-lived fission products. However, the work gave an opportunity to develop ideas about the pulmonary behavior of the most abundant of the fission products.

A schematic of the apparatus used in the pile, modified slightly from the one major report prepared on this early inhalation work, is shown as figure 9.2 (Scott

et al. 1945). In addition to the products of neutron bombardment of the foils, the mixture included also the normal radioactive gases, such as radioxenon, circulating in the pile.

FIGURE 9.2. Schematic diagram of apparatus for in-pile production of short-lived fission products and animal exposure manifold. (Redrawn from Scott et al. 1945.)

Both pieces of work suggested that the principal descendants from the emanation mixture inhaled by the animals were strontium and barium, plus rare earths and zirconium, which were found in soft tissues.

With the in-pile system, the composition of the mixture could be varied somewhat by manipulating the hold-up time in the reactor. Elimination time from the upper respiratory tract was very rapid. (Nine-tenths of the original activity was either absorbed or eliminated by sixteen days.) Small differences in clearance occurred with different hold-up times. The deeper lung sometimes cleared less rapidly. Most of the soft tissues held only small amounts of activity, and this was lost rapidly. Thyroid accumulated very large activities initially, presumably from absorption of radioiodine, but it left rapidly enough so that after a few days thyroid was usually comparable to other soft tissues. Only skeleton retained significant amounts over the longer periods. Feces were the predominant route of excretion, with urine significant only at early times. This latter may represent excretion of the more soluble entities present in the initial mixture.

Most of the subsequent inhalation studies were done at Berkeley rather than at the pile (at least the reports do not indicate to the contrary) and involved either an aerosol spray, burning of thin metal foils, aerosol production in an electric arc between graphite rods, or sparking in a high voltage discharge.

This work was published in condensed form in 1949 (Scott et al. 1949) by most of the authors of the earlier progress report (Scott et al. 1945). This seems to be the only formal report from this fairly extensive amount of work. The authors regarded both the techniques and scope of the work as preliminary and placed

less emphasis on it than on the mainstream work utilizing other routes. Nevertheless, the outlines of much of the future of inhalation toxicology can be discerned in the results, and they deserve more than passing mention.

Most of this later work used either fissionable material like uranium or plutonium, fission products that had aged for appreciable periods, or a mixture of the fissionable material and fission products or separated elements. For the fission mixtures there either had to be, or the investigators chose that there be, appreciable periods of aging between removal from the reactor and the actual inhalation experiment. Thus, this work differs from the earlier work at the cyclotron and the pile by involving primarily the longer-lived fission products and some of the important alpha-particle emitters.

The specific aerosols and a glimpse of the production techniques are given in the following excerpt from the cited publication.

The specific aerosols used in these studies were prepared as follows:

1. Plutonium nitrate as $\text{PuO}_2(\text{NO}_3)_2$ is soluble in ethyl ether. Advantage was taken of this property by introducing the plutonium nitrate into the exposure chamber as a spray. Very small particles free from ether were produced by forcing the ether-plutonium solution through a gold jet after it had been allowed to come into equilibrium with carbon dioxide at a pressure of 760 pounds per square inch (53 Kg. per square centimeter). An effervescent ether-plutonium solution was produced when the jet was directed into the warm exposure chamber, the temperature causing the ether to evaporate. The plutonium yielded to the rat was about 10 per cent of the total plutonium per exposure. The exposure time was 3 to 4 minutes. . . .
2. Aerosols of plutonium in the plus four state as plutonium oxide (PuO_2) were produced by burning the plutonium salts and the plutonium metal itself. In the former instance, the solution was evaporated on graphite electrodes, and in the latter the metal was embedded in holes drilled in the centers of the 1/16 inch graphite rods. In both cases the electrodes plus the plutonium were burned in an atmosphere of oxygen in an electric arc. Two hundred micrograms of plutonium were burned for each exposure. The amounts yielded to the rats varied from 4 to 7 per cent of the material burned. . . .
3. Aerosols of fission products occluded in uranium as uranium oxide (U_3O_8) and plutonium as plutonium oxide (PuO_2) were produced in a similar manner. At the time of exposure the radiations from the fission products predominated. The ratio of fission product disintegrations to the alpha particles arising from the uranium was about 20,000 to 1. The age of the fission products was 2 to 3 months. About 80 mg. of uranium metal was burned at each exposure of 30 seconds' duration. The yield to the rats was about 1 per cent.
4. Carrier-free fission products were also prepared as an aerosol by evaporating the uranium-free solution on graphite rods and burning these. The solution of fission products used was 6 months to 1 year old. Owing to this fact, the fission products with short half-lives had decayed away. The fission elements remaining then were composed primarily of Sr^{89} and Sr^{90} , Y^{91} , Zr^{95} , Nb^{95} , Ru^{106} and Ru^{103} , Cs^{135} , Ce^{144} , and element 61¹⁴⁷.
5. Zr^{89} was used in a study of a human subject (one of us). The short half-life of this material, as well as the absence of long-lived radioisotopes, precluded any danger of excessive amounts of radiation to the subject. The active material was suspended as an aerosol in argon as follows: The Zr^{89} solution was evaporated on two concave gold buttons 1 cm. in diameter. It was then dispersed in argon by passing 15,000 volts between two electrodes which were placed 5 mm. apart. A 0.01 microfarad condenser was connected across the high voltage line. Oxygen was avoided in the chamber because of the production of undesirable amounts of ozone. Approximately 1 microcurie of Zr^{89} was inhaled by placing in

the left nostril a short rubber tube which was also connected to the generator. The inhaled Zr^{89} was exhaled through the mouth into a glass wool filter, followed by several breaths of inactive air, so that the percentage of material exhaled could be calculated.

6. Carrier-free protoactinium, which has a 30 day half-life, was prepared as an aerosol by sparking evaporated Pa^{233} solution on a gold electrode in a high voltage electric discharge. This was administered to rats in the same manner as Zr^{89} .

Except in the Zr^{89} and protoactinium studies, the size of the particles produced by the aerosol generators was determined by collecting representative samples on amyl acetate films. The particle size was estimated with the aid of an electron microscope.

(Scott et al. 1949, pp. 4,6)

The exposure chambers were each on the same plan, i.e., made of metal with an annular arrangement of holes to accept the nosepiece from the animal. They are diagrammed in the publication cited and will therefore not be reproduced here.^(a) The section of the chamber for the arc or spark "explosion" seems perilously close to the animal array, but the authors make no mention of problems except that the arc was produced in a pure oxygen atmosphere to avoid production of dangerous amounts of carbon monoxide. Heroic measures were taken to guard against entrance through the mouth by sealing and sewing the lips together under anesthesia.

Particle sizes were measured, but the results given are as an average with range rather than by the conventions now used, so that the size distribution can only be guessed at. On the whole, the smokes had typically submicronic average diameters, but the range was sometimes quite large (e.g. 0.06 to 38 μ for PuO_2 [NO_3]₂ in the electric arc). The "spray" produced by evaporation of an ether solution was reported as having an average particle size of 0.25 μ with a range from 0.01 to 0.6 μ . None of this work involved quantities likely to assume the characteristics of "dusts," i.e., larger average particle size.

Rather extensive autoradiographic work was done on both the aerosols and the tissues.

The results can be generalized as follows:

1. Many substances that were readily absorbed into the body and went, for example, to bone after parenteral administration were not readily absorbed from the lung. Instead, they formed insoluble complexes which were usually cleared out rapidly by the ciliary clearance mechanism. Sometimes a portion remained in the deeper lung for appreciable periods.
2. The major depositions were in the upper respiratory tract and were moved out promptly by the normal clearance processes.
3. The investigators were evidently surprised at the mobility of some materials from the alveolar regions.
4. Except for a hint that particle size might influence subsequent behavior, as well as deposition, the materials once through the lung barrier seemed to distribute to the tissues much as after other routes of administration.
5. Nevertheless, the behavior of inhaled materials could not be predicted. Thus, there could be no substitute for information obtained by inhalation experiments.

(a) Units of similar plan were designed at Chicago, and since these have not been published, they will be pictured, and a comparison will be made in the next section.

6. The difference in lung absorption between plutonium nitrate spray and the plutonium oxide aerosol underscored dramatically that even a given element might behave quite differently in different chemical forms.
7. Lung clearance can soon lag behind that from the upper respiratory tract. In fact, there is essentially no long-time residence of these materials in the upper tract.
8. The experiments were all at tracer rather than effects levels, and none went beyond sixty-four days after administration.
9. Larger average particle sizes resulted in greater deposition in the head, less in the deeper respiratory tract.
10. Ruthenium and cesium were very rapidly eliminated and were not retained in the skeleton.
11. Using plutonium oxide, it was determined that about 75% of the material entering in a single inhalation remained in the body. The particles exhaled were 0.5 to 1.0 μ in diameter. (A special valve system was constructed for this experiment.)
12. In the single human inhalation study, using zirconium, almost all of the inhaled activity was retained. Rats retained a lesser fraction (about 70%).
13. Lung clearance via the ciliated epithelium seemed to occur at about the same rate for all substances tried. All the materials fell within a relatively narrow band on a graph of elimination as a function of time.
14. In these experiments there was little evidence that the materials entered the lymphatic system.

To conclude this brief discussion of the Berkeley work, we refer to studies using the intratracheal method of placing materials in the lung. Such work is described by Hamilton in a monthly report issued in February 1945 (Hamilton 1945). The autoradiography indicated very uniform distribution of ruthenium in alveolar sacs and ducts, while distribution of zirconium and columbium was completely random. Yttrium, cerium, fission mixture, praseodymium, and neptunium showed intermediate behavior. There was no material in the trachea or bronchial tree. On the whole, the tissue distribution was similar to that after parenteral administration. This latter indicates that the intratracheal insertion of a solution into the lung is not a suitable surrogate for the more cumbersome and difficult inhalation experiments. Scott et al. indicate an awareness of this point, but it is not emphasized.

A graph showing the percent retention of eight elements as a function of time up to sixty-four days is reproduced from the Hamilton report as figure 9.3. Note that there are real differences in both initial deposition and in clearance after the intratracheal administration of these substances. A similar graph made from the inhalation experiments would show faster clearance because much of the material is deposited in nasopharynx and bronchi, from which clearance is uniformly rapid. Also, the differences among elements would be less noticeable. The primary difference might be the greater mobility of the fission products of plutonium, compared to plutonium itself, even when introduced together as a single aerosol.

Nothing is said in the descriptions of the Berkeley work of any measures taken to guard against the health hazards to the operators of purposely producing a radioactive aerosol, even if in a closed system. Presumably these matters are buried away somewhere in the records of the health physics or health and safety operations of the day. In light of the elaborate precautions taken in the

FIGURE 9.3. Percent of total retained activity deposited in the lungs following the intrapulmonary instillation of carrier-free fission products. (Redrawn from Hamilton 1945.)

postwar development of radioactive inhalation programs, this hiatus must reflect, in part, the characteristic drive in the Manhattan Project to get the information as rapidly as possible, in order to provide guidance to those planning and operating the production facilities. Yet, it is certain that personnel protection was considered.

C. Inhalation Work at Chicago Under the Manhattan Project

1. Commentary

There was much more inhalation work done at the Metallurgical Laboratory installation in Chicago than is generally realized. The bulk of the work is contained in monthly reports and in detailed specialized reports in the "CH" series. Essentially none of the work was published in the open literature. Several

reports were indicated as destined for the "Plutonium Project Record," which later became part of the National Nuclear Energy Series (NNES). Nine reports on inhalation work with "CH" and "MDDC" numbers were slated for publication in volumes 22G and 22H of the NNES. These were among the three volumes in the Chicago series that never reached publication. (See "NNES Hiatus" in Appendix C). For this reason, and because of the extensive and detailed studies involved, the work will be reported here in more depth than might otherwise be necessary, as was done in earlier chapters concerning other unpublished Chicago work (cf. chapters 1, 6, and 7).

The early Chicago work had a common denominator with Berkeley around the potential problems of the radioactive off-gases from reactors. It is difficult to assess the degree of collaboration that took place. The problems of radioxenon kicked off the Chicago reports, just as they did those from Berkeley. And there clearly was collaboration around concerns for the potential exposures at the Clinton Pile. However, the bulk of the work and reports from Chicago give every indication that most of the developments were fairly isolated from Berkeley, and vice versa. With tight security in effect, it is likely that only those in the highest echelons knew the broad picture. Even if there was knowledge at the working level, it would be unlikely to appear in written reports.^(a) Whatever the reason, there is much duplication in the inhalation work of the two laboratories. However, it was more extensive, more methodical, and appeared to occupy a more central position in the program at Chicago, features that have not been obvious heretofore.

In preparing this section, this author has had a plethora of resources. The story was seen in its very early stages by the acquisition some years ago of a complete set of monthly summaries of "Group Experiments" from May 1944 through November 1945, prepared by Dr. R. Abrams.^(b) This set includes hand-drawn graphs and occasional calculations. It was supplemented by copies of the Met Lab declassified monthly reports from May 1943 on, many short reports on special subjects obtained from several sources (Berkeley, Oak Ridge, Argonne, Battelle, and the files of Dr. Hymer Friedell), and the selected review items in the chapter on Chicago work in Friedell's book (Friedell, in press).^(c) Finally came the summary reports written for the "CH" and "MDDC" series.

This report provided an especially good opportunity to see the evolution from what seemed at times to be halting, somewhat repetitive, and haphazard probings into various aspects of the problems, to a final product that is highly organized and crisply pertinent.^(d) This difference between the day-by-day events and the much later refined reports and publications is remarked upon also by Friedell.

(a) An exception is some remarks in a Chicago report on the methods used by Hamilton for the inhalation of short-lived fission products at the reactor.

(b) The typewritten portions are identical with the declassified monthly reports seen in Dr. Friedell's files, but the notes have, in addition, the personal touch.

(c) Manuscript for book seen in draft form. This author is most grateful to Dr. Friedell for sending a prepublication copy of this volume, as well as for an opportunity to peruse his report files and make excerpts from them.

(d) Obviously, this phenomenon is not unique to the wartime research efforts. It applies, to some degree, as we all know, to the evolution of all research into new territories. However, the presence of security restrictions amplified the phenomenon for the Manhattan Project work.

2. Aerosol Production Methodologies at Chicago

Abrams and his coworkers labored so consistently at the problems of producing aerosols of radioactive materials that more is said in the Chicago reports on this subject than in those from any of the other inhalation programs.^(a) For this reason, we should take time to review what they did and what they found.

Almost every monthly report contained a paragraph or so on the attempts to prepare reproducibly an aerosol that would reach the experimental animals in sufficient quantity and of the correct particle-size range to produce measurable depositions in the respiratory tract. It was a dreary recital of discouragements. The amounts of radioactive materials were minuscule at the start of the program. Method after method deposited the bulk of the aerosolized elements on the chamber walls, or left it behind in the generator. Thus, most of the early trials utilized techniques intended to produce vapors, e.g., carbon arcs, high voltage sparks, high-energy condenser discharges, burning of thin wires coated with the material or made of the material, etc. Aerosols of soluble substances were produced by a variety of liquid atomizers.

In contrast to the Berkeley group, the Chicago workers hoped to aerosolize enough material to produce biological effects, as well as to measure tissue distribution and excretion. This made the low efficiency of the methods especially discouraging. Yet, the effort when summarized in an MDDC report in 1946 is impressive (Abrams et al. 1946a). The basic outline of this report covered the following topics:

- Production of Aerial Dispersions
 - Dry Dusting
 - (a) Waring Blender
 - (b) Elutriator
 - (c) Elutrimizer
 - (d) Insufflator
 - Atomization of Aqueous Solutions
 - Atomization of Non-aqueous Solutions
 - Incinerator
 - Production of Aerosols in a Carbon Arc
 - Production of Aerosols in a High Voltage Spark
 - Production of Aerosols in a High Energy Condenser Discharge
 - Production of Aerosols in a Chemical Explosion
- Quantitative Estimation of Air-borne Radioactive Material
 - Measurement of Air-borne Particles—The Ultramicroscope
 - Methods of Collecting Particulate Matter from Air
 - (a) Filter Paper
 - (b) Electric Precipitator
 - (c) Thermal Precipitator
 - Analysis of Collected Samples
 - (a) Estimation of Concentration
 - (b) Estimation of Particle Size

An idea of what the authors thought most worthy of comment can be obtained from the abstract of the cited report, which is quoted below:

(a) The Rochester program, which dealt with aerosol problems in depth, was working primarily with uranium dust, a very weakly radioactive substance.

The biological program calling for exposure of animals to air-borne radioactive materials made it necessary to develop procedures for producing aerosols, exposing animals to the aerosols, and measuring particle size and concentration. Since carrier-free materials were used, techniques were devised for the remote control handling of material with negligible weights, but with high radioactivity so as to obtain maximum deposition in the lungs of the experimental animals.

Of a number of methods of producing aerosols that were investigated, three were extensively used. Atomization of aqueous solutions in a right angle jet atomizer was useful for tracer. But because of the great dilution with air it was not possible to obtain high efficiency. Burning a salt in a D. C. carbon arc was adequate for obtaining high intensity fission product smokes, but failed with Pu where it was necessary to use larger masses of material. High concentration Pu smokes were obtained by wrapping Pu metal in thin aluminum foil and discharging a high energy condenser (1000 joules) through the foil.

To maximize lung deposition and to avoid skin contamination and ingestion we use anesthetized rats which breathed from a small chamber through glass cannulae. This chamber consisted of a 2.8 liter brass cylinder from which 32 rats breathed while lying on a surrounding bakelite superstructure. In the case of the exploding foil it was necessary to use a 4.1 liter cylinder with a partition which protected the rats from the violence of the explosion.

A number of methods were investigated for collecting smoke samples for analysis. The most satisfactory was the thermal precipitator which makes use of the dust-free zone around hot bodies to precipitate all the particles in a sample of air on to a Parlodion-coated microscope cover slip. Concentrations were estimated by doing direct α and β counts on these cover slips. Later the Parlodion film was stripped off the glass and mounted for particle size observation in the electron microscope. Mean particle size with the methods used in our experiments averaged 0.1 to 0.2 μ . (Abrams et al. 1946a)

The details of these methodologies are largely of historical interest. We now have better methods. Yet, a few notes on what happened are pertinent.

The methods for handling dry dusts, e.g., elutriator, elutrimizer (a combination elutriator and atomizer), and the conventional insufflator required too much material to be useful for any but low-specific-activity materials such as uranium oxide. Only a small amount of work was done at Chicago on inhalation of uranium compounds.

The carbon arc finally worked well for fission products and uranium, but never could produce high concentration plutonium smokes. The electrodes had to be of as pure carbon as possible since a large proportion of the aerosol was made up of volatilized alkaline earths and carbon particles from the electrodes. Fortunately, the autoradiographic method made it possible to work out sizes of the radioactive components. The size of the chamber was critical. If it was too small, the animals were too near the arc. If it was too large, most of the material was lost to the chamber walls. A diagram of the carbon arc system used most is shown as figure 9.4.

Plutonium smokes were not satisfactory from the high voltage spark. They were prepared at useful concentrations with high-energy (37,500-volt) condenser discharges. Unfortunately, the explosion produced by this sudden release of energy required a chamber divided into two sections. The aerosol was produced in an upper section and diffused to the animal array connectors by opening a door to the lower section. This reduced efficiency and thus the yield.

The atomization of water-soluble solutions produced satisfactory aerosols only after much experimenting with details of the atomizers, such as the angle of entrance of the jet from the solution reservoir. One of the best of these was

FIGURE 9.4. Diagram of cylindrical "merry-go-round" chamber for the exposure of rats to arc aerosols. The chamber was a brass cylinder 6 in. in diameter and 6 in. high, and was seated in a slight depression in the center of a circular Bakelite shelf 26 in. in diameter. A second such Bakelite shelf was mounted 2 in. above the lower one and was removable so that one had free access to the lower shelf. The entire unit of shelves and chamber rotated on a brass pivot, being balanced by small brass wheels under the lower shelf. About 1/2 in. above each shelf 16 uniformly spaced holes through the chamber were filled with 1/8 in. rubber grommets. On each shelf 16 anesthetized rats were laid supine, and tracheal cannulae projecting from their mouths were pushed into the chamber through the grommets. The bottom of the chamber was covered with a layer of CaCl_2 , soda lime, and Hopkalite to control humidity, CO_2 , and CO . Carbon electrodes were mounted through Bakelite insulators along the axis of the chamber. (Redrawn from Abrams et al. 1946a, pp. 33-34.)

one designated as Type II. This is diagrammed in figure 9.5A. However, these were made of glass and were hard to duplicate and to clean. To avoid having to decontaminate the jet and use it over, Abrams and colleagues turned to a simple metal jet that could be discarded. A diagram of this is shown as figure 9.5B. Either unit could be attached to an exposure system such as that shown in figure 9.5C. Since plutonium is soluble in some organic liquids, attempts were made to derive aerosols of plutonium from them. Freon did not work well, but the "ether bomb," in which plutonium is dissolved in dimethyl, or diethyl ether, was moderately satisfactory. For reasons that are not clear, the method did not seem to work as well as the similar one used by Hamilton and colleagues at Berkeley. However, the efficiency requirements the Chicago people placed upon themselves were more demanding than for the work at Berkeley done at tracer levels only.

Particle sizes were usually reported in terms of the average with range. However, with some aerosols, e.g., ^{144}Cs from a carbon arc, the size frequency distribution and a probit plot were given in the manner being adopted by the aerosol scientists working in other fields.

It can be seen that the production of aerosols of radioactive materials presents some unique and difficult problems. Most of them were associated with the very small mass of material to be used, brought about early by the scarcity

FIGURE 9.5A. Right angle jet atomizer, Type II. It was necessary that the stream of dry air be introduced coaxially with the atomizer stream to prevent a cyclone effect from plating all the particles out on the wall. The strong Tyndall effect faded almost completely within a centimeter beyond the mixing point, thus indicating great diminution in surface area, i.e., evaporation. It was usually desirable to have the flow rates of saturated and dry air approximately equal. In most experiments with the Type II atomizer, the air stream containing the radioactive aerosol passed through a manifold to which were attached 21 rats by cannulae inserted loosely into the precipitator. A pump pulled about 20 l/min through the precipitator and through an asbestos filter paper beyond the precipitator. The complete setup is shown schematically in figure 9.5C. (Redrawn from Abrams et al. 1946a.)

FIGURE 9.5B. Right angle jet atomizer, Type III. The capillary feed and conducting tubes were made of metal. (Redrawn from Abrams et al. 1946a.)

of these new radioisotopes, later by the high radioactivity associated with even very small masses of some materials. Even so, it was not uncommon to have millicurie amounts of activity used for single exposure attempts, only to have most of it go to the chamber walls.

As at Berkeley, relatively little is said in the Chicago reports about health protection and contamination prevention measures. There is description of a

FIGURE 9.5C. Manifold technique for exposing rats to aerosols. The mist from the atomizer is mixed with dry air to be passed down the glass manifold into which the animals' snouts protruded. Either the Type II or Type III atomizer could be used. (Redrawn from Abrams et al. 1946a.)

special shield to use for loading hard beta emitters into the carbon arc. Also, it is stated that the exposure apparatus at the piles was probably arranged also for the laboratory work at Chicago. However, the reports are relatively silent on these aspects.

3. Metabolism of Short-Lived Airborne Fission Products

A cooperative effort was carried out at Oak Ridge (Clinton Laboratories) in 1944. It involved in-pile irradiation of uranium foil with gas passing over it to pick up the fission recoil atoms and to carry them to animal exposure chambers and recording equipment outside the shield. The work was written up in May 1945 by Lanz and Teresi (1945) as a CH and later an MDDC report slated for publication in Vol. 22H of the NNE series.

The interrelationships between the work reported from Chicago on short-lived airborne fission products from the pile and the somewhat similar work reported from Berkeley are not well documented. The report of Lanz and Teresi has inscribed on it, "This work was performed at Oak Ridge, Tenn. (Clinton Labs) in 1944."

The puzzling fact is that the 1945 summary by Scott et al. reports Berkeley work with short-lived fission products from the Clinton Pile^(a) with exposures stated to have been conducted between November 7 and December 10, 1944, apparently after the Chicago work.^(b) The apparatus used is the one pictured in figure 9.1. The Chicago apparatus, pictured in Lanz and Teresi, is quite similar. However, the report from Berkeley makes no mention of any preceding work done by people from Chicago or anywhere else. We must conclude that the two laboratories conducted quite similar work at the Clinton Pile, but we can only conjecture whether they were entirely independent or only appear so

(a) This was reviewed in section II B.

(b) Both reports were originally in the classified CH series and later declassified in the MDDC series.

because of the security requirements of the day, which might have governed what was said in a report.^(a) Fortunately, the results, to the extent that they overlap, are not in conflict.

Construction and calibration of measuring and recording equipment are documented in some detail by Lanz and Teresi. Composition of the "hot gas" was found to include 77-hr tellurium, 12.5-day barium, several strontium isotopes, and three radioiodines. The presence of radiotellurium was taken as evidence that solid primary fission products reached the animals.

The biological results soon demonstrated that the external radiation dose to mice exposed to the fission recoil gases accounted for all effects in the lethal dose range. This was concluded from an experiment in a small chamber with the animals immersed in the gas. In addition, rats exposed and set aside for periods of up to a year showed no discernible difference from controls beyond the period of acute effects. This was taken as evidence that the deposited radionuclides did not produce significant effects.

The manifold device described above was constructed to eliminate the external radiation dose except to the nose and mouth of the animal. This would thus allow effects of internally deposited radionuclides to predominate if they could. The only effect seen, in acute experiments, was radiation burns of the mouth and upper respiratory tract. Some of these animals lost weight and died—apparently from starvation brought on by inability to eat. Those animals that lived beyond this period recovered completely for the duration of the experiment, which appears to be about forty-five days. The starvation hypothesis was tested further by giving a normal caloric diet to some of the rats intraperitoneally. Survival was increased sufficiently to suggest that the hypothesis was approximately correct.

Results of gross and microscopic pathologic examination indicated nothing beyond the mouth and nose region. It was concluded, on these bases also, that internally deposited radioactivity played no role. In these days of appreciation of the latent periods required for development of radiation effects, particularly from deposited radionuclides, the observation periods for pathology in these experiments seem ridiculously short. However, the metabolism work, to be reviewed presently, indicates relatively little retention, even in bone, so that an experiment for long-term effects would probably have been negative. The authors' conclusion that the hazard from short-lived fission products is much greater from external radiation than from internally deposited radioactivity is probably correct.

The metabolism work extended to about sixty days after exposure. While loss from the body was quite rapid, there appeared to be a larger proportion retained than in the Berkeley work. This may reflect the different composition of the mixture. About 25% of inhaled material went to skeleton from lung and was excreted very slowly (half-time about two months); of the amount in lung, about 8% was lost slowly; about 6% was excreted slowly from liver. The balance, in each case, left the body relatively quickly. The highest specific activity occurred in the thyroid. Absorption from the gut was much smaller than from the lungs.

Typical excretion curves showed an initially rapid loss via urine followed by approximately equal loss rates in feces and urine. *This contrasts not only with*

(a) The work using cyclotron bombardments at both Berkeley and Chicago mentioned in the previous section, of course, antedated the in-pile irradiations.

the Berkeley work, but with most other work on inhaled fission products. The reason is not clear.

Autoradiographic studies of the lungs showed uniform distribution of these materials over bronchial and alveolar surfaces. This is consonant with the Berkeley work, and both are in contrast to the behavior of plutonium and many mixtures of long-lived fission products. It probably indicates the predominance of gaseous materials in the initial inhaled mixture.

Attempts to increase the hold-up time sufficiently to get a higher percentage of long-lived fission products failed for technical reasons. It was necessary to turn to quite different experimental approaches to accomplish this, as we shall see presently.

4. Work at Chicago with Longer-Lived Fission Products

Monthly reports beginning in April 1944 carried brief reports of work in progress on inhalation of individual longer-lived fission products. The first moderately detailed report concerned carrier-free 330-day ruthenium and radiocerium administered as aerosols. The ruthenium experiment demonstrated the phenomenon of early rapid clearance from the lung. Over 50% was lost in the first day, followed by a much slower rate of loss with a half-time of over thirty days. Further experiments showed that the ruthenium might be changed in valence state in the lung. Ruthenium chloride in +3, +4 valence state was cleared less than half as fast as ruthenium vapor in the valence 8 state (Met Lab Report 1945a, pp. 15-16).

When cerium experiments progressed beyond sixty-eight days of holding time, the beginnings of hypertrophy of lung cells were noted, but no metaplasia. Lung inflammation was spreading and becoming more intense (CH-2904).

In the next month, Wender and Dailey (Met Lab Report, 1945b) added the comment that ruthenium showed little tendency to deposit anywhere in the body, and tended to be excreted almost as fast as it was absorbed from the lungs. They also noted that urine and feces carried about equal amounts with the possibility of a difference between vapor and aerosol.

In the same report, Abrams describes the progress with three-hundred-day cerium. Here a dc arc was used, and an average dose of about 50 μ Ci per animal was given. There was extensive respiratory involvement in enough of the animals that it was concluded this dose was near the LD₅₀ (or what they termed the SD [sick dose] 50).

Abrams and Seibert reported on effects of fifty-seven-day yttrium inhaled as an atomized aqueous solution some seven months before. There was no evidence of damage, even though the initial lung dose was 26 μ Ci. The material was eliminated very rapidly, and the calculated lung dose was about 1,500 roentgens. They turned, instead, to a dc arc in hope of obtaining a more insoluble material. They put 400 mCi of the radioisotope on the electrodes of the arc to accomplish this exposure.

The first major summary of the inhaled longer-lived fission product work came in April 1946. This was a 109-page document that describes work with strontium, zirconium, yttrium, and cesium (Abrams et al. 1946d). It is noted that the work began before the Clinton Pile was in operation, but continued and grew as materials became available. The elements chosen were considered as representative fission products, and all were carrier-free. The report is presented as a chronology, with techniques and their evolution described in each section. A useful feature is the depiction of the fission product chain producing

the given element with half-lives and maximum energy. The strontium isotope was ^{89}Sr , the zirconium isotope ^{95}Zr , the yttrium isotope ^{91}Y , and the cerium isotope primarily the ^{144}Ce - ^{144}Pr couplet. With the exception of strontium, each radioisotope was presented as both a soluble aerosol, from atomization of an aqueous solution, and an insoluble aerosol prepared by burning in the carbon arc.

There were significant differences in behavior among these four elements, particularly between strontium and the other three.

It is expedient to summarize this by extracting from the abstract of the report:

Strontium differs from the other elements investigated in the ease with which it is absorbed from the lungs. Over 50 percent left the lungs within a matter of minutes, and 95 percent was gone within 1 hour. Of the Sr^{89} originally in the lung, 60 percent was deposited in the skeleton in less than 4 hours, and after 12 hours the total radiation dose to the skeleton exceeded that to the lungs. These results indicated that inhalation was as effective a means of administration as intravenous injection, and that lung damage as a result of inhalation of Sr^{89} would be of less importance than bone marrow damage.

The other three elements, Y, Zr, and Ce, may be grouped together insofar as they differ from Sr. They were all eliminated from the lung much more slowly than was Sr. Thus the times required for 90 percent elimination were: Y^{91} , 12 days; Zr^{95} , 25 days; and Ce^{144} , 45 days. In all cases the skeleton was the major site of deposition and eventually contained between 15 and 30 percent of the initial lung deposit. In no case, in periods ranging up to 200 days, did the total radiation dose to the bone exceed that to the lung, as it did within 12 hours with Sr. With all three elements the probability of radiation damage to the lung is great.

Very little deposition occurred in the soft tissues. The kidney contained about 0.5 percent of the dose with all the elements. Concentration in the liver was lower than in the kidney with all isotopes except Ce^{144} . This element showed a very high initial liver deposition, but this was gradually eliminated so that after 2 months the liver concentration fell below that in the kidney.

(Abrams et al. 1946d)

Integrated radiation doses were calculated where feasible. The dose to femur exceeded that to lung within ten days after ^{89}Sr administration. The metabolism data indicate that this might be true also for ^{91}Y , probably only true after longer times for ^{95}Zr and never for ^{144}Ce .

Differences between soluble and insoluble forms were expressed largely in slower elimination from the lungs of the insoluble form. Once absorbed, there was little difference in subsequent tissue distribution. An example of the difference in lung clearance seen with the two forms of ^{95}Zr is shown in figure 9.6.(a)

The very large amount of cerium deposited in liver as compared to the other elements is worthy of note. This was seen also in the Berkeley work.

Autoradiographs of lung and bone were made in a few instances. However, the authors do not remark upon these in detail, and the reproduction makes it difficult to analyze them independently.

Although the metabolism work extended to thirty days, there does not appear to have been any attempt at histopathological examination, or any chronicling of biological effects. It is concluded, nevertheless, that the danger of damage to the lung probably exceeds that to other tissues in these types of exposure.

(a) The number of experimental points shown in figure 9.6 reiterates the fact that much of this wartime inhalation work was range-finding in nature. The tabular material is usually more detailed than the items chosen to present in graphs.

FIGURE 9.6. Relative rates of elimination of ^{95}Zr from the lung following inhalation of atomizer ("soluble") aerosol and arc ("insoluble") aerosol. (Redrawn from Abrams et al. 1946d.)

A frank effects study on a long-lived fission product is seen in an undated report by Seibert and Abrams. (Since it was declassified in September 1946, it could not have been produced later than 1945, and is so referenced.) This work of Seibert and Abrams (undated) concerned the acute toxicity of 275-day ^{144}Ce . Fairly large groups of rats were exposed to smokes produced by the arc technique using tracheal cannulation. There were five groups that received doses of 3.2, 14, 39, 50, or 200 μCi per rat. All but one group utilized the exposure apparatus described in section II C 2. Weight loss was significant only at the highest exposure, and these animals had a median survival time of 39 days. The median survival time at the level of 39 μCi per rat was 282 days, while 90% of the animals given 14 μCi were alive at 300 days.

The distribution in lung of ^{144}Ce was quite irregular in contrast to zirconium, and it was also irregular in the liver. On the other hand, cerium was distributed throughout bone cortex in contrast to zirconium and plutonium.

Acute inflammatory reactions were described in lung, but they were variable in both extent and progression with time. Cervical lymph nodes and the tip of the spleen nearest the lung showed direct effects similar to external radiation. Both thymus and spleen showed cellular depletion. There were small changes in bone marrow and kidney, practically no changes in liver, heart, adrenals, gut, and pancreas. Some squamous proliferation of bronchial epithelium was noted.

Radiation doses were calculated to the several tissues and compared to the dose of external radiation with which the observed effect could be associated. No differences appeared that would correlate death with dose to any single tissue, although obviously the lung was a prime candidate.

A study reported in 1945 on 1.0-yr ruthenium can close our consideration of the Chicago work with inhaled long-lived fission products. This is termed a tracer study, but actually concerned chemical toxicity as well as distribution and excretion of the radioisotopes.

The abstract of this report reads as follows:

This paper deals primarily with the fate of tracer quantities of airborne ruthenium after inhalation by rats.

1. In the course of the work it was necessary to have a simple, quantitative test for Ru, and a colorimetric test was developed which depends on the blue color formed with rubeanic acid. It was possible to detect 2 μg of Ru with 10 percent accuracy.
2. In order to expose animals to RuO_4 vapor, a generator was needed which would supply RuO_4 at a continuous and more or less uniform rate. Of a number of oxidizing agents investigated for this purpose, potassium permanganate in sulfuric acid was best suited.
3. A rough determination was made of the chemical toxicity of Ru for mice. By intracardiac injection, doses in the range of 3 $\mu\text{g/g}$ were acutely toxic.
4. Methods have been developed for assaying tissues for radioactive ruthenium. The hard β of the 1.0 year Ru - 30 sec Rh system is counted. To avoid volatility losses, small tissues are minced, dried at 110°, and counted. Larger tissues are muffled and a correction made for losses due to volatility.
5. Three types of Ru exposure were carried out: to RuO_4 vapor, dry " RuCl_3 " aerosol, and " RuCl_3 " solution. In all cases the Ru was rapidly absorbed from the lungs and rapidly excreted via the urine and feces. The kidney tends to retain a considerably higher concentration than other tissues. The rapid excretion, approximately 90 per cent in 30 days, minimizes the hazard resulting from internally deposited Ru.

(Dailey, Wender, and Abrams 1945)

This work appeared piecemeal in many monthly reports and is probably chronologically older than much of the other Chicago work cited in this section. It gives an excellent review of the properties of stable ruthenium and ruthenium tetroxide, radiochemical properties of the several isotopes, a colorimetric method for quantitative analysis of stable ruthenium, and the distribution of the one-year isotope in the tissues of rats. The problems of devising atomizers and chambers are also included, and the study is topped off by exposure to a " RuCl_3 " solution by intubation. They conclude that it is the one-year ^{106}Ru + rhodium daughter couplet that is most important energetically. However, because of very rapid excretion, hazards from internally deposited ruthenium of the types used in these experiments were considered minimal when compared with other fission products. The presence of a significant potential for chemical toxicity is worthy of note, and the Chicago workers deserve kudos for investigating this often neglected possibility with radioisotopes, even though it does not control in this particular instance.

5. Plutonium

Inhalation work with plutonium at Chicago developed more slowly than the work with fission products. This was partly because of the lag in availability of the element (see chapter 7) and partly because of the disheartening technical problems of producing useful aerosols of plutonium, discussed briefly in section II C 2 above. The monthly reports seen in Dr. Abrams's file (cf. section II C 1) mention plans for inhalation experiments with plutonium as early as June 1944.

This was only a few months after allocation of the 10 mg of precious cyclotron-produced plutonium to Joe Hamilton at Berkeley in late January 1944. In July 1944, a note is made of attempts to work with dry plutonium as the cupferron complex, and aerosol production by a Freon bomb technique is described. By August, the influence of valence state is mentioned. Nevertheless, the problems of getting a plutonium aerosol produced with sufficient efficiency to allow studies of biological effects and reproducibility predominated these progress reports.

By January 1945, enough tracer work was done to allow concluding that the valence IV state remains in the lung much longer than either valence III or valence VI. In February, they reported on arc-produced aerosols of a zirconium-plutonium mixture, on the large effect of complexing with citrate, and they drew the conclusion that the nature of the inhaled compound can have as much effect on distribution as the mode of administration itself. In the spring of 1945, the metabolism of plutonium was followed up with the conclusion that valence IV plutonium could remain in the lung for long periods, with major deposition sites after absorption being the liver and skeleton. This latter allowed some tentative cross-correlations between these inhalation experiments and the further-advanced intravenous work at Chicago and elsewhere.

However, even in spring and summer 1945, when the Chicago workers wanted to place a known dose of plutonium in the lung, they resorted to intratracheal intubation (instillation). A complete report prepared for the PPR^(a) volumes draws all of this work together (Abrams et al. 1946b). It brings in Herman Lisco as pathologist and Leon Jacobson as hematologist, names we have already seen associated with much of the biomedical effort at Chicago in chapters 6 and 7. Their presence meant that the aerosol people had finally gotten effects. Even though the short-circuit route of intratracheal administration is not a perfect substitute for inhalation, the results were important.

First, the tight binding of plutonium in the lung was found to occur also after this mode of administration. A quarter of the dose was still present after 210 days.

Second, the skeleton retained the major portion of the plutonium that left the lung via the bloodstream.

Third, damage to the lungs was extensive and considerable. The doses ranged from 7.5 to 500 μg per 200-g rat (0.5 to 31 μCi per rat). Even the lowest dose produced progressive pulmonary damage, characterized by inflammation, necrosis, and abscess formation. Animals surviving a month or longer showed persistent, acute and chronic inflammation; emphysema; and in many animals "a striking squamous metaplasia of the bronchial epithelium which often showed remarkable proliferative activity."

Fourth, toxicity of plutonium entering by the lung appeared significantly greater than the same dose given intravenously. Table 9.1A, taken from the Abrams et al. (1946b) paper, illustrates this point, and table 9.1B shows the calculated radiation doses to lung and skeleton.

Note that the difference between intrapulmonary and intravenous toxicity increased with time. The "median lethal doses" in table 9.1B are expressed in terms of the organ concerned and thus vary with plutonium content of the organ. They are probably not very meaningful, except to show the very large radiation dose imparted to lung and that lung dose exceeded bone dose by a

(a) Plutonium Project Report, the earlier name for the NNEs volumes.

TABLE 9.1. Acute Toxicity of Plutonium by Intratracheal Instillation in the Rat

A. Median Lethal Dose (LD₅₀)					
	Time After Administration (days)	Median Lethal Dose ($\mu\text{C/g}$)			
		Intrapulmonary	Intravenous		
	30	0.081	0.062		
	60	0.025	—		
	90	0.013	0.062		
	150	0.006	0.050		

B. Median Lethal Dose, Δ_M					
Dosage Group	Dose ($\mu\text{C/rat}$)	Median Survival Time (days)	Δ_M , Lung (rep)	Δ_M , Skeleton (rep)	Lung/Bone
A	0.5	203	2,600	340	8

C	4.3	67	15,000	570	26
D	13.00	24	29,000	310	93
E	31.00	26	72,000	840	86

Source: Reset from Abrams et al. 1946b.

Note: The "rep" unit was used for several years for situations in which the roentgen did not apply. The letters stood for "roentgen equivalent physical." For our purposes, we can equate it approximately, but far from exactly, to the rad.

factor of eight, even at the lowest level. It was over eighty times the bone dose at Level E.

This experiment was probably the first to highlight the special effectiveness of plutonium in producing lung damage. We will see the same general phenomenon in the postwar work where carcinogenesis is the primary criterion.

The authors speculated that the consolidation, hypertrophy, and abscesses in lung contributed to the high retention of plutonium. While this was undoubtedly true, later work at lower concentrations exhibited avid lung retention without such extensive pulmonary damage.

There was very little deposition in liver in these intratracheal intubation experiments.

The pathologic changes in tissue other than lung were inconsequential relatively, although significant hematological changes occurred in the groups receiving 24 and 70 μg per rat (observations began approximately fifty days after administration). The dose of 7.5 μg per rat produced no significant deviations from normal over a two-hundred-day period. The changes, when seen, involved moderate anemia, preceded sometimes by an initial elevation in erythrocyte count, plus the usual decreases in lymphocytes with return toward normal at the intermediate doses. The hematological effects were less marked than those following equivalent doses given by either the intramuscular or intravenous routes. This difference was attributed to the retention in lung and lesser participation of this plutonium in the production of hematological changes.

The high retention in lung and the extent of damage produced therein are held responsible for the high lethality of plutonium in this experiment.

The 1945 monthly reports contain increasingly frequent reference to true inhalation experiments with plutonium, primarily experiments on metabolism. Something must have begun to go right with aerosol techniques for plutonium, or the investigators decided to go ahead with what they had. The efficiency remained low, but plutonium was no longer scarce, and they could thus afford larger initial quantities. Unfortunately, the accuracy and reproducibility of the dosage never even came close to the intratracheal intubation technique. Yet, the noted differences in deposition kinetics and subsequent tissue distributions between inhalation and intubation made experiments with inhaled aerosols essential.

The bulk of the Chicago experimental work on inhaled plutonium is contained in a report prepared in October 1946 by Abrams and colleagues (1946c). This manuscript was slated for one of the PPR volumes (NNES) that was not published (Appendix C).

The source of the plutonium was given as the Chemistry Division of the Metallurgical Laboratory. It very likely came from a reactor at Clinton Laboratory.

Nearly all of the exposure techniques described by Abrams et al. (1946a) were used. These were basically atomization of the soluble forms and development of oxide smokes either in a carbon arc or by exploding a plutonium metal foil wrapped in thin aluminum foil by a high-energy condenser discharge.

This was all distribution and excretion work using primarily the rat. The system never reached the point of permitting effects levels on inhalation of plutonium. The chief virtue of this work is the increase in numbers of experiments and numbers of points per experiment so that the major findings can be considered dependably demonstrated. Effects of valence state were confirmed. Even using "soluble" aerosols, tetravalent plutonium was comparable to the most insoluble of the fission products. Indeed, elimination from lung seemed to cease altogether after about two months, with about 10% of the initial dose tightly bound. Plutonium (VI) showed an initial period of rapid loss, but after about five days behaved like plutonium (IV). It was postulated that the VI state was converted to the IV state *in vivo*, a conclusion that has stood the test of time.

Skeleton, the major site of deposition of absorbed plutonium, carried about 20% of the initial dose. Unlike the findings with parenteral routes of entry, the liver did not usually even approach skeleton in content, either early or late. In fact, liver and kidney were close together in most cases. With plutonium (III) given as the nitrate, liver was slightly higher than kidney. However, none of the results showed the almost equal division of plutonium between liver and bone described in postwar work using the parenteral route of entry.

The second major set of experiments with inhaled soluble plutonium at Chicago concerned the effect of complexing. The agents used were cupferron, citrate, and Calgon (a metaphosphate detergent of the day).

Cupferron had relatively little effect on the rate of elimination from the lungs, but it did have a striking effect on skeletal retention, i.e., 7% at 110 days versus 20% in the absence of complexer. Also, absorption seemed to be poorer. Both of these earmarked cupferron as a possible therapeutic agent for plutonium poisoning. However, this idea seems to have fallen by the wayside.

For the study of citrate and calgonate, the investigators returned to intratracheal intubation because they wished a "more reproducible initial dose." Citrate had dramatic effects. Plutonium citrate was even more mobile than the

soluble nitrate salts. Indeed, combining with citrate had effects that outweighed differences in valence so that Pu (IV) and Pu (VI) citrate behaved quite similarly. Deposition of the citrate in both skeleton and liver was rapid and large. The deposit in liver left quickly, however.

Calgonate was not a particularly effective complexing agent in terms of its effect on tissue distribution after intubation.

The inhalation of plutonium oxide smokes did not add much new to the story that was not already known from other sources. However, the experiments were the longest reported in the Manhattan District inhalation series at Chicago; they extended to a full year. They demonstrated clearly the continued extreme insolubility of plutonium-oxide and almost quantitative deposition in the lung and upper respiratory tract. Since the particle size was quite small, nearly all of the smoke was of respirable particle size. Soft tissues accumulated negligible quantities. There was, however, considerable elimination from lungs after these smoke depositions, and significant, though not large, transfer to skeleton.

The figures, given as percent of initial dose per organ or as percent of initial dose per gram of tissue, are shown in table 9.2A and B.

TABLE 9.2A. Distribution of Inhaled Plutonium Oxide in the Rat

Source: Reset from Abrams et al. 1946c.

These figures should be kept in mind for comparison with the more sophisticated postwar experiments since the smoke form may well be more likely encountered in occupational or accidental exposures than aerosols with larger mean particle sizes.

The feces were the main route of excretion. It is of interest that the fecal excretion rate, up to eighty-four days at least, corresponded closely to the rate of elimination from the lungs. The very much lower urinary excretion rate seemed to parallel the loss rate from liver. This, too, should be earmarked for comparison with later work by both inhalation and other routes of entry.

Quite logically, Abrams et al. conclude that the smoke is predominately a hazard to lung, whereas the hazard to lung from "soluble salts like the nitrate is distinctly less." Since no formal effects studies were done in the plutonium inhalation experiments, the possibility of bone damage could not be checked out. However, the concentrations in skeleton after inhalation of the soluble salts bespeak the possibility of biological damage.

6. Histopathological Data from Bloom

Bloom received a few specimens from the inhalation experiments for histopathological examination. The paragraph concerning the inhalation work, which appeared in the chapter on lung in his classic book in the NNES series (Bloom 1948), is reproduced below. Note that it includes plutonium.

A few rats were available for the study of lung tissue after inhalation of yttrium 91, cerium-praseodymium (275-day), or plutonium. Control rats were divided into two groups. Both groups were given an anesthetic, and cannulas were inserted into the tracheas of the second group only. Experimental rats, in addition to the anesthetic and the cannula, received 28 or 220 microcuries per rat of yttrium 91 (AY), 50 microcuries per rat of cerium-praseodymium (275-day) (ACB), or 1.5 to 31.5 microcuries per rat of plutonium (APME). Seibert and Abrams discuss the probable distribution of inhaled particles of cerium-praseodymium and plutonium. The experimental animals showed effects similar to those seen in the controls, with a further striking reaction of the bronchiolar epithelium. In the experimentals the regrowth was more extensive. Although in the yttrium 91 and cerium-praseodymium (275-day) series the epithelium did not go beyond the confines of the basement membrane, many bronchioles contained several layers of spindle cells. Some of these grew with their long axes surrounding the vessel, and in other areas there seemed to be no orientation. In a specimen from a rat sacrificed one month after inhalation of plutonium, the growth of epithelial cells appeared suggestively neoplastic (Figs. 15.1 and 15.2). One of the three rats killed six months after inhalation of cerium-praseodymium (275-day) appeared normal; the other two contained extensive epithelial cell proliferation. Whether the final disposition of these cells is toward cancer or the normal condition cannot be stated. However, it is certain that these animals reacted positively in their bronchiolar epithelium to the inhalation of radioactive materials. The reaction was more extensive and for a longer period than the reaction of those animals exposed to nonactive substances.

(Bloom 1948, pp. 707-708)

7. Recap of the Chicago Inhalation Studies

The rather considerable amount of work done on inhalation of fission products and plutonium at both Chicago and Berkeley did not have the same impact on the field as the parenteral administration work reviewed in chapters 6 and 7. This was partly because of the technical difficulties and the lower degree of confidence in the results that this engendered in the investigators themselves. It

was partly due to the fact that less work was done. Reviewed in light of the enormous postwar enterprises, the results are not all that bad. They established a firm beachhead and pointed the way with general conclusions that have stood up.

A significant point of contrast between inhalation and parenteral administration seen in this work is, besides the obvious involvement of lung, the small amounts of plutonium deposited in liver.

D. Inhalation Work at Rochester

Two completely separate sets of inhalation experiments were carried out at the University of Rochester School of Medicine and Dentistry during the Manhattan Project days. They were in separate divisions of the project. Because of the tight security, the work and reports thereon were almost completely isolated from each other, although it seems unlikely that the large installation of exposure chambers could have been completely isolated and unnoticed. The work involved inhalation of smokes of ^{210}Po on the one hand, and the inhalation of uranium dusts and gaseous uranium compounds, such as the hexafluoride, on the other hand.

1. Work with Polonium-210

This work was carried out under the Biological Chemistry Section of the Division of Radioactivity in the Manhattan Department of the University of Rochester.^(a) It was reported in classified reports and in the NNES volume edited by Robert Fink (Fink 1950) and was part of the major effort on alpha-emitting radionuclides discussed in chapter 4 of this book. The authors of the inhalation section are C. P. Kimball and R. M. Fink (Kimball and Fink 1950).

A technique generically similar to that used for producing fission-product and plutonium smokes at Chicago and Berkeley was employed, but with differences in detail. All exposures involved evaporating a droplet of polonium onto a nickel foil, which was heated by passage of an electric current until it burned out. Since polonium is quite volatile, there were few problems with the efficiency of aerosol production, although there is no doubt that appreciable quantities plated out in the apparatus. No particle size analyses were made. The technique used for generating smokes usually produces relatively small particles.

There were two systems set up for nose-only exposure to volatilized polonium entrained in an air stream. The first was a straight-through system attached to a suction sump. The second was a closed system of small volume. These are pictured in the cited reference (Kimball and Fink 1950) as figures 2.28 (p. 90) and 2.31 (p. 97). In both, the rat's snout was in fairly close proximity to the foil.

The third system was a somewhat heroic attempt to separate inhaled from exhaled air in order to measure directly the amount of airborne polonium exhaled and to compare this with the amount deposited in the body. Dead space in this system was nil since both ingress and egress were through nasal cannulae. One cannula was inserted in one nostril and one in the other. The experiment was done under deep anesthesia. There were two versions of this system, but neither worked very well. The cannulae easily became plugged with

(a) Remember that the Rochester Project was not part of the Metallurgical Laboratory portion of the Manhattan District Corps of Engineers.

nasal secretions, and it was difficult to get sufficient air through the system. The results were quite variable. Initial deposition was predominantly in the lungs using the straight-through apparatus, about equally divided between lung and nasal passages with the closed system. Amounts in selected tissues at twenty-four hours and ten days after administration are shown in table 9.3 using data from the more extensive tables in the Fink volume.

TABLE 9.3. Amount of Polonium in Tissues After Inhalation. Average of two rats. Percentage of dose.

Tissue	24 Hours		10 Days	
	Whole Tissue	Per Gram	Whole Tissue	Per Gram
Lungs	30.4	20.1	5.5	4.6
Intestine	18.6	2.7	3.1	0.2
Skin from head	12.8	4.0	0.8	0.4
Skin, except head	5.9	0.1	3.9	0.1

Liver	1.4	0.2	4.3	0.5

*One rat only.

Source: Reset from tabular data given by Kimball and Fink 1950.

Note: Numbers have been rounded off.

As might be expected, lung tissues are far ahead of others at twenty-four hours and maintain the position of having the most polonium at ten days, but not by such a large margin. Note that the *concentration* (percentage of dose per gram) rises significantly in kidney, spleen, and blood cells between one and ten days.

Since a primary point of interest in doing these experiments was to ascertain the tissue distribution of polonium entering from the lung compared to other routes of entry, a comparison has been put together as table 9.4.

TABLE 9.4. Percentage of Dose Per Gram of Polonium in Selected Tissues of the Rat

Tissue	24 Hours		10 Days		
	Inhalation	Intravenous	Inhalation	Intravenous	Oral
Lungs	20.1	0.9	4.6	0.8	0.03
Intestine	2.7	0.7	0.2	0.6	0.01
Kidney	0.7	3.6	1.8	4.3	0.05
Spleen	0.8	5.1	2.3	9.3	0.1
Blood Cells	0.4	2.3	1.0	1.2	0.2
Bone	0.07	0.4	0.1	0.4	0.01
Liver	0.2	1.7	0.5	1.3	0.01

Source: Reset from numbers in Kimball and Fink 1950.

Note: Averages have been rounded off.

These are concentrations (percentage of dose per gram of tissue). Note that differences appear between inhalation and intravenous routes in kidney, spleen, liver, and blood cells, as well as lung, at both one and ten days. The figures for oral administration are complicated by the fact that there is far from complete absorption of the administered dose from the gastrointestinal tract (see chapter 4).

It can be speculated that polonium entering the blood stream from lung is more likely to be monatomic, or at least in much less aggregated form than that entering via intravenous injection. The considerable amount of colloidal or semicolloidal material present after intravenous administration is taken up by the reticuloendothelial system (RES) cells in spleen and liver.^(a)

Thus, at least up to ten days, there are some quantitative differences in the tissue distribution of inhaled polonium versus injected or ingested. Nevertheless, the investigators were more impressed with the similarities than the differences among the routes of administration, except for lung. Furthermore, it appears that volatilized polonium, presumably an oxide, is largely absorbed into the blood stream from the lungs, but that a small fraction remains as noted below.

An experiment was conducted specifically to determine loss rates from lungs and upper respiratory passages. Instead of nose-only exposure, this experiment was done in a large chamber (glass jar) which would allow simultaneous exposure of fifteen to twenty rats. The results, shown in figure 9.7, were unexpected. Although clearance was initially rapid from all the sites measured, an appreciably greater amount remained in lung than in upper respiratory passages or on the skin of the head.

FIGURE 9.7. Retention of polonium deposited in lungs, upper respiratory passages, and skin of head of rats after exposure to volatilized polonium. (Redrawn from Kimball and Fink 1950, p. 108.)

(a) The kidney and blood cell concentrations represent other processes (chapter 4).

These results are reminiscent of the phenomena seen with insoluble oxides of plutonium and fission products. They suggest that even relatively soluble materials, such as most of the compounds of polonium, can be bound in lung moderately tightly.

Excretion was measured by putting a few animals in metabolism cages. Average cumulative excretion of inhaled polonium in urine, over a ten-day period, was 3.1% of dose after inhalation, only 0.8% of dose after intravenous administration, and 2.1% of dose after oral administration. Ten-day totals for fecal excretion were 66.1% of dose after inhalation, 25.2% after intravenous entry, and 98.6% (a) after oral administration.

Calculations of total absorption indicated that more polonium is absorbed from the lung into the blood stream than after administration of a comparable amount by stomach tube.

Autoradiographic pictures were made of volatilized polonium in the lungs. These showed, initially, fairly uniform distribution in alveolar tissues, except toward the outer borders of the lobes. Bronchial linings showed clearly. By twenty-four hours, only a little polonium was left on the bronchial walls, while the location of dense activity had spread slightly farther into the alveolar tissues.

The Rochester work with inhaled polonium did not carry beyond ten days or into the realm of effects. There were relatively few animals. They were exposed individually, except for the one experiment to determine respiratory-tract loss. The amounts of polonium deposited in the animals varied from animal to animal sufficiently to discourage attempts at setting up any study of effects. They do, however, suggest that inhaled polonium will, except for the involvement of lungs, distribute qualitatively like material received intravenously, but with some quantitative differences.

Again, as in the work at Berkeley and at Chicago during these wartime years, relatively little is said about the safety precautions instituted in generating these smokes. However, the exiting air streams were usually bubbled through from one to several wash bottles in tandem. Polonium is soluble enough in the acid used in the open-end system, or strong alkali used in the closed system to absorb CO_2 , to make it unlikely that significant quantities got out of the apparatus.

2. Uranium

The work at Rochester on inhalation of uranium, under the Manhattan Project, concentrated on compounds of natural uranium. An overview of the entire program is given in chapter 2, including details of the long-term postwar experiment. The MED work was presented in depth in four book-length reports in the National Energy Series (hereafter called "The Uranium Monograph"). It was in two distinct sections, one published in 1949, the other in 1953.

The methodology for inhalation exposures differed from that used at Chicago and Berkeley and for the polonium work at Rochester in that it could draw much more upon the fast-developing field of industrial hygiene than could the methods used for the more highly radioactive materials. Dust feeds and relatively macro amounts of material could be used. Analyses were largely by

(a) The fact that urine and feces account for over 100% of the dose in this case is within experimental error and reflects the relatively poor absorption from the gut.

chemical methodology rather than radioactivity. The biological endpoint was chemical toxicology, primarily kidney damage, with some lung damage at high concentrations.

a. Development of the Program

The Manhattan District Corps of Engineers and its predecessor organization, OSRD,^(a) were convinced from the start that some of their earliest health problems might center around the handling of uranium. After all, uranium ore had to be treated and several compounds made before any of the next steps in the development of the project could proceed. Also, they were convinced that the prime route of entry would be inhalation.^(b)

As soon as the Rochester Project was organized, a program was mapped out to do inhalation toxicology on twelve different uranium dusts (eleven different compounds and one ore dust), and to ascertain very acute toxicity (one day), acute toxicity (thirty days), and longer-term or chronic toxicity (one year). All exposures were continued for the period named. Effects were observed over longer periods in some instances.

The background against which this ambitious program began is described quite clearly in the beginning of the inhalation toxicology chapter in the first of the NNE monographs by Voegtlin and Hodge (1949). There was essentially no previous information available on inhalation of uranium dusts per se.

The pressures to learn something were tremendous. Work began almost immediately. An example of some of the crude experimental beginnings was given in chapter 2.

In January 1944 (the project began in spring 1943), it became apparent that the buildings, equipment, and personnel could not begin to keep pace with the urgent health problems expected to arise in the handling of uranium or even with the fast-developing requirements of the experimental regime itself.^(c) Approach to longer-term toxicity studies seemed as far away as it had at the outset of the work. Yet, this was one of the chief concerns. Important decisions had to be made. These were as follows:

1. The acute, chronic, shorter-term, and longer-term exposures would be done as nearly simultaneously as possible rather than awaiting the results of one before proceeding to the next. Also, some planned experiments on acute toxicity would be omitted.
2. A new wing was to be constructed on the project buildings, largely to accommodate exposure chambers, additional personnel, and animal care facilities. This additional facility is the one-story building at the right of the picture of the early Rochester Project building shown in figure 2.1 of chapter 2. It was quite deep and contained a surprising amount of space.
3. On completion of the new facilities, the entire operation was to go on a two- or three-shift-per-day basis. This involved not only the exposures, but the supporting and collaborating functions, such as hematology, pathology, analytical chemistry, biochemistry, physiology, surgery, statistics, etc.

(a) Office of Scientific Research & Development

(b) Remember the "Green Hornet" we met in chapter 2.

(c) Additional work involving toxicology of fluorine and of special materials related to the toxicology of uranium had been piled onto the already overwhelming burden.

4. The staff was augmented by assignment of many additional military personnel who had from considerable to essentially no training in science, as well as by recruitment of civilian scientists wishing to contribute to the war effort.
5. Frequent joint planning sessions and conferences were held. Each exposure study was carefully examined and planned, both by discussion and by circulation of detailed memoranda.^(a)
6. Personnel were divided into teams around each animal-exposure unit, with a Ph.D. biomedical scientist in charge, who was aided by three to five assistants with M.S. or B.S. degrees. Only the animal care away from the chambers devolved on other personnel.

As a result of this semimilitary organization^(b), important data began to accumulate quite rapidly and, thanks to a laudable compulsion for follow-through on the part of Harold Hodge, Herbert Stokinger, Aser Rothstein, C. W. LaBelle, and many others mentioned as authors of the Inhalation Toxicology chapter in the NNEs monograph, the goals were reached. Not only were the experiments completed, but the strengths and weaknesses of inhalation work were carefully analyzed.^(c) While numbers do not guarantee quality, it is impressive to note that during the three-year inhalation program at Rochester, more than twelve thousand animals were involved. Seven species contributed: rats, dogs, rabbits, guinea pigs, mice, cats, and hamsters. This array was, of course, far beyond anything possible in the programs with smokes and mists described earlier in this chapter. Indeed, it suggests the need for some sort of memorial to these thousands of animals that contributed in their way to the war effort.

b. Exposure Chambers

The chamber designs for the Rochester uranium work leaned toward large size. They were, after all, looking for effects in addition to distribution and excretion and needed to expose significant numbers of animals for each run. Nevertheless, they utilized both the nose-only mode and whole-body exposure. The design was based in part upon a survey of installations at the Dow Chemical Company, the National Institute of Health of the U.S. Public Health Service, the Kettering Laboratories, and the U.S. Bureau of Mines, but they soon assumed characteristics and identities of their own.

The Rochester chambers ranged downward in size to two all-metal construction units donated by the University of Pennsylvania for special tests. Materials varied from wood and glass with transite lining, through wood-framed metal units, to all-metal units for the more corrosive dusts and vapors such as uranium hexafluoride.

Naturally, chambers of this size could be used only with a relatively abundant material of low specific activity, such as natural uranium. Uniformity of distribution of the aerosol within the chamber was a major engineering challenge. It seems to have been met adequately for the work at hand. Details of the cage racks, rubber neck-gaskets, etc. are given in the published monographs. Despite appearances, these exposure rigs were relatively comfortable for the animals, who would frequently sleep during the exposure.

(a) Security could be kept by utilizing code names and numbers in any general conference and in the written documents.

(b) Further details can be seen in chapter 10 of Voegtlin and Hodge (1949).

(c) As we saw in chapter 2, much besides inhalation work was going on, but the chapter describing it is by far the longest in the monograph (277 pages).

c. Dust Feeds and Sampling

A variety of dust feeds were tested out before exposures since the properties of the twelve uranium compounds varied considerably. There was a pressure feed device (figure 10.6, chapter 10, Voegtlin and Hodge 1949), which had the same principle as some of the mist generators, described earlier, but which introduced solid material to the air stream. A modification of this was a ball-mill dust feed, which ground the powder in situ just before it was taken into the air stream to the exposure chamber (figure 10.7, Voegtlin and Hodge 1949). An agitated illutriator reminiscent of the device developed at Chicago worked quite well on dry dusts (figure 10.8, Voegtlin and Hodge 1949). Feed systems for UF_6 had to handle and introduce a corrosive vapor. The prime need here was exclusion of all possible water vapor (figures 10.9-10.11, Voegtlin and Hodge 1949).

Dust concentrations produced by these various methods were established in most studies by a filter-paper dust sample run at constant air flow. This sampler was modeled after the unit being used at the National Institute of Health, Division of Industrial Hygiene, by L. T. Fairhall and colleagues (for example, Fairhall and Sayers 1940). It was modified so that samples could be taken at any location in the chamber, rather than just at the wall of the unit. This allowed checking the uniformity of distribution of the dust. The samples were subjected to chemical analysis, and frequency-distribution curves of dust concentration were plotted. These showed the mean level, its relation to the desired level, and the distribution of points for both low-level and high-level exposure modes. In general, the range was smaller around the lower-level mean than around the higher-level mean. This information was essential for effects studies where the occurrence of pathologic responses some months hence was in question.

d. Particle Size Determinations

The Rochester investigators put a tremendous effort into both determination of particle size and studies of the effects of particle size. This went far beyond the consideration given to particle size in either the Berkeley or the Chicago work. This was partly because they were using by and large true dusts with a considerable range of particle sizes and, thus, also of relative respirability, and partly because the larger amounts of material made such work more feasible.

They looked at the air centrifuge, the photographic ultramicroscope^(a), and the cascade impactor. The greatest emphasis, by far, was on the cascade impactor. This device was developed in England for the work of the British Chemical Warfare Service at Porton. It was first described in the open literature by May (1945), but the Rochester people got details earlier through the Scientific Research and Development Section of the British Ministry of Supply and the U.S. Army Chemical Warfare Service.^(b)

(a) At this time, electron microscopes were scarce and were just entering the field. They were used later on in the MED studies at Rochester, but seem not to have entered as early as at Berkeley and Chicago.

(b) British-American collaboration in the field of atomic energy was smooth up to 1945. It was always good in aerosol research, at which the British were topnotch. In some other areas, such as sharing the ultimate secrets, they were not very smooth for a while (Hewlett and Duncan 1969), despite very significant early contributions by the British on the theoretical side.

Briefly, the device depends upon impingement of dust from jets of different sizes onto microscope slides, with each stage separating, to the extent possible, one range of particle sizes from another. The slides could then be photographed and the sizes counted, or the amount of material thereon simply weighed to give the proportion of the total dust on each stage, a great advantage in both time and convenience. There was usually some form of back-up filter to collect the ultrafines.

The uranium monograph gives full details of the original British cascade impactor and its use, including particle size distributions by optical measurement, by chemical analysis, calibration, design problems, etc., as well as a modified cascade impactor, which the Rochester people developed to overcome some of the problems of the British unit, such as durability in routine use and adaptability to uranium dusts. Also, the Rochester group found that size measurements and counts on the resin-coated impactor slides were not satisfactory. They developed a technique for selenium coating, in high vacuum, to obtain a high refractive index mounting. Details of this are given in chapter 10 of the uranium monograph.

The compendium from Rochester (uranium monograph) probably represents the most comprehensive description anywhere between two covers of the use of the cascade impactor for a specific set of dusts along with the full details for calibration and modification.^(a) It also is rich in details of the trials and tribulations as well as the successes of particle size determination during the years of World War II under the Manhattan District program. The identification and concentrated use of the cascade impactor were major contributions to the sophistication and usefulness of the Rochester inhalation experiments. The device has now come into quite general use, of course.

e. Relation of Particle Size to Toxicity

Earlier work, cited in part in the Rochester reports and in part in the general industrial hygiene literature, made clear that particle size could influence profoundly initial deposition in various segments of the respiratory tract, and to a lesser extent, the rates and degrees of lung clearance. At Rochester, LaBelle (1949, 1953) spearheaded an investigation of the influence of particle size on toxicity after deposition in the lungs. To do this he used carefully fractionated suspensions of UO_2 dust, which he administered by intratracheal instillation. Measurements were made of weight changes in the animals, of blood nonprotein nitrogen, kidney function, histological changes in lung and kidney, and the uranium content of selected tissues at one, two, and four weeks after administration. Maximum toxicologic response was seen at one week. The toxic effect varied inversely with the particle size. Particles of UO_2 smaller than $1\ \mu\text{m}$ were inherently more dangerous than larger particles. Also, transport out of the lungs and deposition in the femur increased with decreasing particle size. These seldom-quoted results are reproduced as figure 9.8.

(a) This device and its proper use became so much a part of the Rochester inhalation toxicology mystique that it was taught in-depth to health physics and industrial hygiene students in the postwar years. A seven-hour lecture hall session by one over-enthusiastic instructor not only turned some of the students off on aerosol techniques in general, but almost triggered a student revolt, which it became this author's duty to pacify. Dust can be dangerous in some unexpected ways!

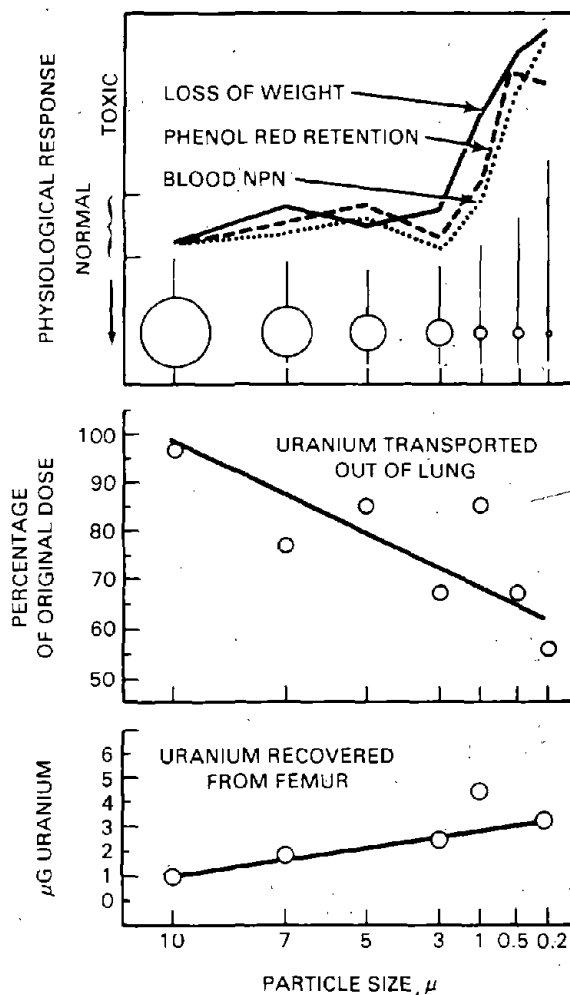

FIGURE 9.8. Changes in toxicologic responses and body transport of uranium in rats following intratracheal injection of 30 mg UO_2 /kg of body weight in graded particle sizes. Upper, retention of phenolsulfonphthalein dye (phenol red), body-weight changes, and changes in nonprotein nitrogen of blood; middle, transportation of uranium from lung; lower, deposition of uranium in femur. The circles in the upper figure give the relative size of the particles as if they were spherical. (Redrawn from Voegtlin and Hodge 1949, p. 510.)

An experiment with similar purpose, but using true inhalation, was performed near the end of the MED Project days. Preliminary results were published in the open literature by Wilson et al. (1948), and a fuller follow-up, done apparently partly postwar, was presented by most of the same authors several years later (Wilson, H. B. et al. 1955).^(a) This experiment used uranium triauroxide dust

(a) Further work was also described in the second part of the NNES compendium.

(U_3O_8) instead of uranium dioxide (UO_2). Since the aerosols were not monodisperse, only two "points" were available rather than the several seen in figure 9.8. The dispersions had mass median diameters of $0.5\ \mu\text{m}$ and $2.5\ \mu\text{m}$. Both rats and rabbits were used. The results were qualitatively similar to those of the intratracheal experiment. The particles with a mass median diameter of $0.5\ \mu\text{m}$ were much more toxic at the same concentration as evidenced by increased urinary protein, retardation of growth, and renal damage seen by histopathological examination. Deposition in lung, kidney, and femur were also greater with the smaller-particle-size aerosol, but subsequent redistribution was not affected. Surprisingly, the authors do not indicate whether or not they considered the difference in toxicity as fully explainable by the greater retention of the small sizes in important organs. Indirectly it can be concluded that they did not think so. The possibility that the smaller particles are more easily oxidized to higher oxides of uranium, which are more toxic, was speculated upon in some depth as a possible explanation for the greater toxicity of the small particles, i.e., it might have been due, in part, to a chemical difference. Indulgence in such possible explanations would not be expected if the difference in tissue concentrations explained the matter completely in the minds of the investigators. Incidentally, effects of the $2.5\text{-}\mu$ average mass median diameter were only marginal in the rabbit, and insignificant in the rat, while those of the $0.5\text{-}\mu$ range were significant in both species. The U_3O_8 dust concentration was $80\ \text{mg}/\text{m}^3$.

There were a few minor differences between the UO_2 intratracheal study and the U_3O_8 inhalation study. Nevertheless, the similarities were sufficient to indicate that *in this setting* the intratracheal method was a satisfactory substitute for inhalation once the differences in deposition in lung and upper respiratory passages had been accounted for.

This work on the effects of particle size per se on ultimate toxicity was unique in the MED work.

f. Biological Results in the Rochester Inhalation Studies with Uranium

The reader is reminded again that the biological endpoints of this uranium work were manifestations of chemical toxicity, primarily in the kidney, plus any systemic signs that proved useful. They are detailed extensively in the uranium monograph. They included periodic weight checks, chemical analyses of blood and urine, hematologic changes, and terminal gross pathology and histopathology. In addition, the uranium content of tissues was measured. Several physiologic tests, such as renal clearance in the dog, biopsy of renal tissue, liver function, etc. were applied selectively. Each compound, each exposure, and the peculiarities of each experiment are reported upon in depth. Each section is written by the investigator responsible for that segment of the work. Yet, because of the ubiquitous planning sessions and capable guidance, these disparate efforts form a coherent saga that needs only summarization in these pages.

Now let us have a broad summary of the results of this prodigious effort on biological effects. The basic biological changes were described in chapter 2. Summary results applicable specifically to acute inhalation exposure are shown immediately below; they will be followed by a summary of the effects of chronic exposure.

Table 9.5 gives a summary of acute toxic responses following daily inhalation of uranium dusts. The period of exposure was thirty days.

TABLE 9.5. Summary of Acute Toxic Response of Animals Following Repeated Daily Inhalation of Uranium Dusts

Approximate Concentration Level of Dust, mg/cu m	Response to	
	UF ₆ , UO ₂ F ₂ , UCl ₄ , UO ₂ (NO ₃) ₂ , 6H ₂ O	UF ₄ , high-grade ore, UO ₂
20	Generally fatal to most species; severe renal and frequently pulmonary damage	Occasionally fatal to some species; mostly moderate renal damage; severe renal damage in certain species only
2.5	Fatal to certain species; severe to moderate renal damage; occasional pulmonary damage	Nonfatal or rarely fatal; mild or no renal damage
0.2	Fatal to an occasional animal; slight renal damage in certain species	
0.05	Nonfatal; no histologic damage	

Source: Reset from Voegtlin and Hodge 1949, p. 688.

The soluble forms (left side of table) produced more effects at the high concentrations, and their range of effectiveness extended to much lower concentrations than that of the insoluble forms (right side of table).

Table 9.6 presents the "no-effect" levels in these same experiments. The presence of such a level presupposes that there is a threshold for response. In the radiation field, we have become habituated to thinking that no threshold exists for many of the critical biological effects. This is certainly not so true of chemical toxicology, and not true at all for the effects on the kidney, of primary interest in acute uranium poisoning. Thus a "no-effect" level has much more meaning for uranium than for strongly radioactive materials.

TABLE 9.6. Uranium-Dust Levels Producing Minimal or No Histologic Changes in the Kidney of the Dog

Dust	Lowest Level Showing Mild, Transitory Response, mg U/cu m		Highest Level Showing No Detectable Response, mg U/cu m	
UF ₆ , UO ₂ F ₂ , UCl ₄ , UO ₂ (NO ₃) ₂ , 6H ₂ O	0.2		0.05	
High-grade ore	1.0			
UF ₄	3.0		0.8	
UO ₂	10.0		2.0	

Source: Reset from Voegtlin and Hodge 1949, p. 688.

It will be noted again that the “insoluble” forms differ from the “soluble” forms, but along a more graded scale than the data in table 9.5 would predict. In the text, the authors state that “complete freedom from response upon repeated exposure to the soluble dusts is not attained until the level of 0.075 mg of uranium is reached. By contrast, the insoluble dusts produce no injurious effects at levels of from approximately ten-fold to thirty-fold higher concentrations” (Voegtlin and Hodge, 1949, p. 688).

A third measure is the toxic response score. The twelve uranium dusts were graded from UF_6 (most toxic) to U_3O_8 (least toxic) on a grid, shown in chapter 2 as figure 2.5.

A very full effort also went into *chronic* exposure experiments. While most of the actual exposures were done during the days of the Manhattan Project, the full-length published documents did not appear until 1953 (Voegtlin and Hodge, 1953). We will consider these chronic studies and their reports as part of the MED effort, even though final analyses and probably the bulk of the writing were under the Atomic Energy Commission (AEC) auspices.

It takes another 408 pages in the second pair of uranium volumes in the NNES series to present the chronic inhalation work and another 59 pages to present work using insufflation. The third and fourth parts of the uranium monograph, usually referred to as Part II,^(a) are devoted entirely to reporting all aspects of the chronic studies. There were eleven inhalation experiments of one-year duration and one two-year study. The primary reasons for this enormous extension of the work was establishment, as closely as possible, of a uranium dust concentration in air that would never produce even slight evidence of renal injury in an occasional animal. However, there were many secondary objectives, both scientific and practical. These can be seen best by excerpts from the introduction to the chapter on Chronic One-year Inhalation Studies:

Problems for the 1-year Study. The acute studies, however, left some important questions unanswered. Was apparent recovery complete, or would continued exposure produce a transition to a chronic form? Or would there be produced a series of acute attacks each followed by repair? Closely associated with the concept of chronic uranium toxicity is that of tolerance. Does the tolerance that was demonstrated to follow repair of acute renal injury in the short-term studies persist during continued exposure for 1 or 2 years at lower dust concentrations, or is acquired tolerance and chronic toxicity the same entity? Perhaps of greatest importance in long-term exposure is the storage of uranium in the body. Is it of such a degree as to constitute an injurious chemical accumulation or a possible radiation hazard, or does elimination keep pace with intake? At what sites of the body is deposition most marked; and how is this related to the solubility of the compound? There was obvious need for further, more prolonged studies. The chronic experiments described in this chapter were designed to fulfill this need.

(a). Aim of Chronic Studies. The objective of the chronic studies differed in one major aspect from that of the acute studies. Whereas emphasis in the short-term studies was placed on levels producing demonstrable injury, emphasis now was to be placed on the assignment of dust concentrations that would either

(a) All these “volumes” are considered as Volume I of Division VI but had to be bound in four parts, all labeled “VI-I.” Physically they are volumes, but they must be considered officially parts of one volume. One reason for this awkward arrangement is that the second phase covering the chronic work was not part of the original plan, and the uranium work, in toto, had been assigned as Volume I of Division VI (Rochester) of the NNES. Small asterisks on the cover tell readers which part they have in hand.

ensure a safe exposure for 1 year or produce minimal or borderline injury in the more susceptible members of a species. This objective was highly important since it would provide a measure of the required increase in concentration to produce minimal response over that required to produce none. The measure of this spread thus would provide information on the safety factor for each compound. To achieve this end it was obviously necessary to make at least two studies of each compound at different concentration levels. Moreover, because much time and expense went into such experiments, the number of studies had to be limited. The number of test compounds was restricted to five. Their choice was based upon three considerations: (1) the magnitude of the industrial exposure, (2) the representative nature of the compounds in regard to their physical and chemical characteristics, and (3) their relative potential contribution to fundamental toxicological knowledge. (From Voegtlin and Hodge, 1953, p. 1372)

In addition to meeting these practical objectives, many quite basic and universally applicable findings ensued as described in chapter 2.

The number of animal species used routinely was decreased to two, but the size of the experimental groups was increased. Much additional work on particle size was done. The single two-year study was operated by continuing exposure of animals from an insoluble dust exposure to a soluble compound at a higher level. There was an opportunity to perform serial pathology experiments so that the gradual development or the waxing and waning of lesions could be followed.

Even the essence of the results cannot be extracted in the space at our disposal. The reader will find the details clearly set out and identified with each experiment in the pages of the monograph. A few highlights can be set down here:

1. There was a distinct and typical response in the kidney to the one-year exposure that was qualitatively different from the thirty-day acute exposure. Whereas in the acute situation the animal either died or recovered fairly rapidly (and the kidney damage was repaired), in the chronic situation damage was relatively permanent. At high concentrations, it could progress beyond nephrosis to fibrosis of the kidney, but on the whole the changes were not markedly progressive.
2. At higher concentrations, the lung could be involved, sometimes to the extent of causing the animal's death.
3. The liver was sometimes involved, but never critically, at even the highest levels.
4. There was no evidence of radiation damage.
5. No neoplastic changes or frank cancer were reported. (Little is said about cancer in this work, but it is presumed that the pathologists were alert to its possible occurrence.) This may mean that one year is still much too short a time to develop cancer from natural uranium exposures (see chapter 2).
6. There is a definite change from acute to chronic injury, but the characteristics of acute injury can reappear. Also, acute injury is a necessary prerequisite for the development of the chronic type injury characteristically seen in the kidney tubules. Thus the "chronic injury" may represent incomplete or improper repair of an acute injury. As implied above, and unlike many types of long-term injury, the uranium lesions did not usually become progressively worse. In fact, even the chronic type injury showed reversal and repair if exposure ceased. *This has important implications for the*

epidemiology of uranium exposures in man and the validity of claims for compensation for exposures long since discontinued.

7. On the basis of over one-half million observations, it had to be concluded that functional changes such as blood or urine biochemistry were more transitory than the morphological changes. They were not nearly as reliable as the information from kidney biopsy or serial histopathologic examination of tissues and were not reliable indices of underlying biological damage.
8. Hematological changes were likewise not a good measure of the presence or absence or degree of chronic injury. While there were changes, they were more transient and more variable than the kidney lesions.
9. Weight change correlated moderately well with development of early kidney damage, but, at later times, weight response was not a reliable measure of the degree or progress of chronic toxicity.

All of these conclusions, even though broadly and qualitatively stated, bear on the interpretation of chronic exposure of man to natural uranium. We reviewed some of the extant dilemmas in chapter 2. We will address the issue further in chapter 16. Suffice it for now to point out the marked difference in progression of the lesions and in the ability of the organism to handle moderately toxic levels of uranium compared to the more radioactive materials such as plutonium and other transuranics, polonium, and the fission products.

g. Deposition and Retention of Inhaled Uranium (Chronic Exposures)

We reviewed in chapter 2 the fact that uranium is a bone-seeking element and the general features of its metabolism; here we will look briefly at its behavior on and after inhalation. We will adopt the conventions of modern inhalation toxicology and use "deposition" to refer primarily to the amount of inhaled material deposited in the respiratory tract and "retention" for the behavior after deposition. For what was frequently called deposition when absorbed material reaches an organ, other than lung, we will substitute the word "uptake."

The behavior after acute exposures has already been reviewed briefly. We will concentrate here on the most prominent features from the chronic inhalation studies of the MED days.

1. Only a few sites are involved in *deposition* of uranium dusts, viz., lung and its draining lymph nodes. Transfer occurs almost entirely to bone (including the tooth structures) and the kidney, if the salt is relatively soluble.
2. Uptake is primarily in kidney, especially for soluble salts, but kidney does not accumulate uranium. It soon reaches an equilibrium concentration where uptake and loss balance.
3. Bone is the only tissue that accumulates uranium after exposure by inhalation of soluble salts. The accumulation is modified by exposure level. Below 0.25 mg uranium/m³ exposure concentration, there is no appreciable accumulation in bone or any other tissue over one or even two years.
4. Naturally, the very insoluble forms (UO₂) remain fixed in lung and accessory lymph nodes for considerable periods. Amounts as high as 7,000 µg/g were found in lymph nodes, 1,500 µg/g in lung at the end of one year of exposure to UO₂ at 10 mg/m³. The amount in bone, in the same experiment, was about 5 to 10 µg/g and in kidney 1 to 5 µg/g. Thus, the lung and lymph nodes might be considered vulnerable to the insoluble dusts of uranium,

but their sensitivity is far less than that of the kidney (see chapter 2). Also, binding seems not to be so tight that the uranium cannot leave once exposure ceases.

5. Retention of uranium in all tissues but bone is not as avid as we have seen for materials such as plutonium.
6. Of particular interest is the fact that insoluble uranium deposited during a one-year exposure continued to leave the lung despite the fact that a second year of exposure was under way, this time to a soluble compound.

Extensive graphic and tabular summaries are contained in the uranium monograph.

h. A Special Deposition Experiment

A central and difficult problem in all inhalation experiments is determination of how much of an inhaled material is deposited on a breath-by-breath basis. Most estimates rely on immediate sacrifice of a few animals and comparing the amount found in these animals with the amount inhaled as calculated from the chamber concentration and the estimated ventilation rate of the animal's lungs. As part of the Rochester uranium studies, toward the end of the Manhattan Project days, LaBelle et al. (1953) devised an elaborate, and for its time, sophisticated apparatus to determine what fraction of the uranium in a single inhalation was retained. The apparatus was based on a method developed by Drinker, Thomson, and Finn (1928), which was in turn developed from a design by Baumberger in 1923. A diagram of the general setup is given in figure 9.9A, and the special facepiece is shown in figure 9.9B.

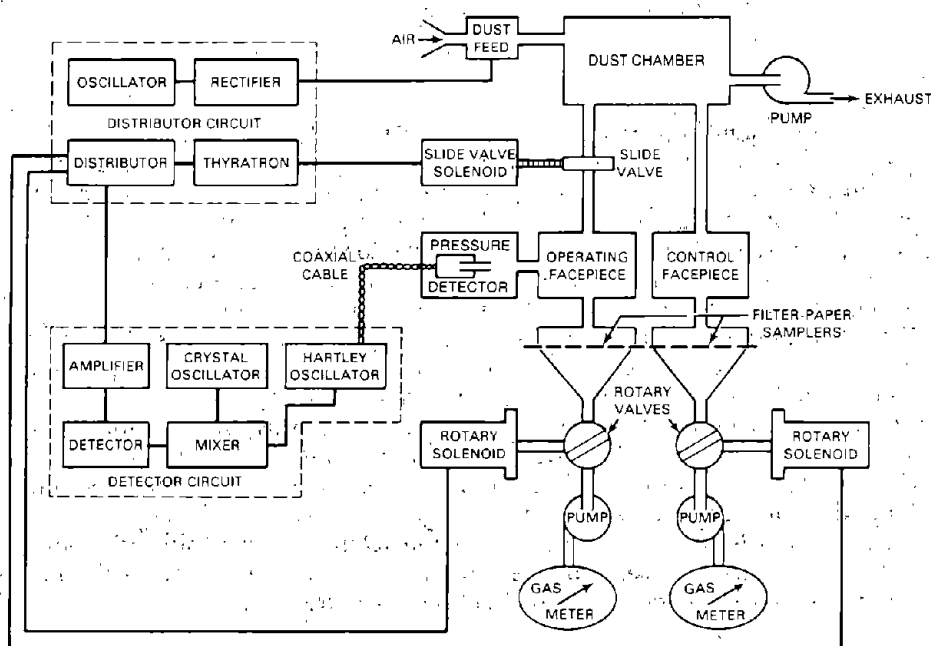

FIGURE 9.9A. General layout of apparatus for retention experiment. (Redrawn from Voegtlin and Hodge 1953; p. 1980.)

FIGURE 9.9B. Diagram of facepiece and valve assembly. CN, nasal cone in which rabbit's head is inserted; CP, opening through which dusty air enters; CE, space into which rabbit exhales; D, duct leading to dust chamber; FP, filter paper on which sample is collected; FR, filter-paper retainer rings; GR, rubber gasket; GS, raised ring to provide seal; R, rotary-valve assembly; RF, flange; RR, rotating plug; RM, T-shaped duct through plug; RS, ducts in valve housing; RQ, hollow quill through which air leaves valve; RB, ball bearing carrying thrust of valve plug; RT, thread to fit rotary-solenoid housing; S, slide valve; SH, slide housing; SR, slide; SC, link to transverse solenoid; T, tap for pressure detector. (Redrawn from Voegtlin and Hodge 1953, p. 1685.)

By means of sensitive circuitry, which activated solenoids attached to slide valves, the very small pressure changes between the end of inspiration and beginning of expiration would cut off the operating facepiece from the chamber, allow collection of expired air, and measurement of its uranium content. The control facepiece (figure 9.9A) allowed collection and measurement of the inhaled air through a path as similar as possible to that entering the operating facepiece. The difference between these was the amount deposited.

The results, using uranium dioxide, indicated that absolute deposition varied as the $3/2$ power of the concentration. Thus, the percentage of deposition increased with concentration and approached 100% at the highest concentrations (range was 10 to 250 mg/m³). Two particle sizes (distribution not given) were used, 0.5 μ and 1.0 μ . There was little difference between them.^(a)

The deposition was directly proportional to the volume of air breathed and independent of the rate of breathing.

Variations in respiratory volume can be equivalent to a five-fold variation in effective concentration. Variation between animals was somewhat less important (equivalent to a factor of two in effective concentration).

(a) A 0.5- μ particle of uranium dioxide is aerodynamically equivalent to a much larger particle of a lighter dust. Thus, the efficiency of impaction of even the smaller particles of uranium in the respiratory tract would be quite high.

There is little doubt that these measurements, done sometime before publication in the monograph, influenced the development of so-called lung models used in establishing maximum allowable concentrations. These will be examined in chapter 16. Hodge (1980) recalled that one of the prime motives for work of this type in the Rochester program was the development of respiratory-tract models. Perhaps these findings were involved in some of the first models developed at the Chalk River Conference in 1949 (chapters 8 and 16).^(a)

i. More Particle Size Versus Toxicity

To cap off this volume-sized report of the Rochester experiments on chronic toxicity of uranium, there is a further detailed report on the effect of particle size on toxicity (LaBelle 1953). Both inhalation and intratracheal instillation of rats and rabbits were used.

The earlier conclusion that smaller particles were more toxic was strengthened. Further, it appeared that $1\ \mu$ was sort of a breaking point. Particles smaller than $1\ \mu$ were progressively more active, and there was no indication that a limit had been reached at the smallest size tested, viz., $0.35\ \mu$. There was not as much change above $1\ \mu$ as below.

This time the investigators really searched for explanations. They found that the variation in quantity of uranium gaining access to the systemic circulation and toxicity correlated well. However, the amount leaving the lung was not a good measure of the quantity entering the systemic circulation, a surprise to the investigators. Appreciable fractions of the uranium dioxide were leaving the lung by some route that did not involve the circulating blood. Furthermore, the removal by this route was such that the *larger* particle sizes were removed more efficiently. We will need to reconsider this dilemma when we review the post-war inhalation toxicology work.

j. Comment

There is no doubt that the strong emphasis on inhalation work in the Rochester program under the Manhattan Project, and the prodigious proportions of the effort, brought inhalation toxicology solidly into atomic energy research. As we will see in the next sections, the momentum carried into postwar research unabated.

Harold Hodge has commented (1980) on the inordinate amount of work involved in many of the inhalation experiments to get only a few points on a graph or figures in a table.^(b) An equivalent effort in many other fields would yield tangible results in much less time. It is fitting, therefore, that the Rochester effort could produce new centers to help carry on the work begun under the pressures of wartime research, as we will see in the following sections.

(a) Like most such conferences, the origin of the values used is not recorded, and is known only to those present. Very recently, Taylor has brought together all of the extant minutes and notes from the Tri-Partite Conferences (Taylor 1984). This yeoman service finally brings at least the substance of the heretofore "private" conferences into public view.

(b) While the same is true of all truly long-term experiments, the inhalation program, with almost daily exposures continuing over months, even years, undoubtedly heads the list for sheer drudgery.

III. The Postwar Years Begin

In striking contrast to the situation during the war years, the new work has been very adequately presented and reviewed. Management had compelling practical reasons for supporting the research and being sure its results were readily available. There was considerable interdisciplinary exchange of interests and ideas between the aerosol scientists and those in radioactive inhalation toxicology (pulmonary radiotoxicology)^(a) on the one hand; and between the people interested in radioactivity and those in conventional industrial hygiene on the other. In some installations, all three types worked closely together. The literature of the field is fairly readily accessible, but it is voluminous. In this section, we will review the major programs, contributions from less major programs, and some areas requiring special attention.

A. Continuing Work at Former Manhattan Project Laboratories

At the termination of World War II, Chicago and Berkeley (i.e., Argonne National Laboratory and the University of California Radiation Laboratory [UCRL]) eschewed almost completely further experimental work in the radioactive inhalation field except some follow-up studies. Of the three prime movers of the war years, only Rochester continued as a center for inhalation toxicology.

Some of the early postwar quarterly reports from Berkeley discussed results of autoradiographic work done to follow up on the aerosol exposures done during the war. Since they were dealing with long-lived alpha emitters, they could go back to some of the tissue blocks prepared in the 1944–1946 work and do new autoradiographic exposures with improved techniques. Results were reported by Asling and Thilo in two UCRL reports (1951, 1952). They were able to emphasize histologic localization of deposition sites and the movement of materials as a function of time after inhalation. They observed not only the evidence of activity concentrated in macrophages and along alveolar walls, but also rather generalized single tracks throughout the tissue. They also noted macrophages in process of apparently disintegrating and releasing their activity. All of these have been seen in other postwar experiments, but these go back the furthest. Examples are shown in figure 9.10A and B.

At Chicago, an extension of the MED work is found in pathology reports by Lisco and Finkel (1949) and by Lisco (1959). Both are firsts. The report by Lisco and Finkel (an abstract) concerns pathology following inhalation of radioactive cerium. It constitutes, it appears, the first report of a lung tumor produced experimentally by the beta particles from an inhaled radioisotope. The 1959 paper by Lisco reports that 50% to 100% of rats surviving 250 days after receiving a $^{239}\text{PuO}_2$ smoke developed epidermoid carcinoma. (The dose was 0.2 to 1.0 μCi .) While not the first report of the production of lung cancer by plutonium, according to Bair (1960), it is the first report of carcinoma after inhalation of a plutonium aerosol. Both reports are cryptic on experimental detail, since

(a) This term was coined by H. D. Bruner for a paper given at a symposium at Sandia Laboratory in Albuquerque in 1967 (Bruner 1967). Dr. Bruner played a key role in the development of the AEC inhalation program. Despite the appropriateness of the term, it seems not to have come into general use. Perhaps too many people were already in the field by 1967 and were calling themselves something else. We will use it here as seems appropriate.

FIGURE 9.10A. Autoradiographic evidence of plutonium oxide within pulmonary macrophages five days after exposure to a plutonium smoke. (Photo courtesy of Dr. Patricia Durbin.)

FIGURE 9.10B. Evidence of aggregated plutonium in lung tissue five days after exposure to a plutonium smoke. (Asling and Thilo 1952; photo courtesy of Dr. Patricia Durbin.)

these reports represent the results of pathological examination of materials from the animals exposed during the war by Abrams et al.^(a)

The work at Rochester in the postwar years can be considered in two parts, that which was a direct extension of the wartime effort and work that was essentially new.

The *direct extension* of the wartime effort into the postwar years was the eleven-year-long uranium experiment, which we reviewed in chapter 2. That experiment assumed heroic proportions. Among other things, it showed that, with sufficient perseverance, radiation effects can be brought about by natural uranium.

A corollary extension of the wartime work was that the Rochester Project became a center for training both for regular academic students and for shorter-term industrial trainees in pulmonary radiotoxicology. As a result, many of the laboratories that developed and came into flower in the postwar years were manned, in part, by people who had either worked in the Rochester program or received academic training there in the early postwar years. Several became laboratory directors or senior scientists in the new programs we will consider presently.

(a) It is rumored that there may be still other left-over material, or was until recently, awaiting the needed analysis by pathologists. Fortunately, such material has a long shelf-life; but the records sometimes become meaningless as the keys to animal codes, etc., get lost, or their interpretation hazy.

A few photographs taken of some of the early postwar classes at work in industrial hygiene and aerosol science at Rochester are reproduced as figure 9.11A, B, and C. More details concerning the Rochester research programs are presented in later sections.

B. Aerosol Science

1. Development of Liaison

The struggles the radioactive inhalation people had during the war in preparing and measuring aerosols were not unique. They were only exacerbated by the technical problems of handling radioactivity. As we remarked earlier, aerosol problems touch upon a great many aspects of technology and research. These fields grew tremendously during and soon after the war, and so did aerosol science. With the lifting of security restrictions, communications took on new dimensions, and the close interrelations between the problems of coal mines, dusty trades, infectious diseases, air pollution, and the radioactive inhalation field were underscored. Particularly industrial hygiene and pulmonary radiotoxicology joined hands.

The field was blessed by the timely appearance and brisk use of many monograph-type books. There was a new edition of the classic book first written in 1936 by Drinker and Hatch entitled *Industrial Dust* (Drinker and Hatch 1954). Soon came a corresponding classic from the east side of the Atlantic, *Particulate Clouds: Dusts, Smokes and Mists*, by H. L. Green and W. R. Lane (Green and Lane 1957). Along with these are important later comers, such as *Particle Size, Theory and Industrial Applications* (Cadle 1965), and *Particle Size Analysis in Industrial Hygiene* (Silverman, Billings, and First 1971). Also in 1971, Mercer, Morrow, and Stöber edited a volume on *Assessment of Airborne Particles* (1972). A very useful volume in the AIHA/AEC Monograph Series entitled *Aerosol Technology and Hazard Evaluation* was produced by Mercer in 1973 (Mercer 1973). Finally, a very fundamental volume on aerosol behavior was prepared by

S. K. Friedlander (Friedlander 1977). This last is a text prepared by Dr. Friedlander from notes for his advanced undergraduate-graduate student course at the California Institute of Technology. These books provide ample general reference material. Perusal of these should satisfy any reader that the physicochemical aspects of the field have been well quantified; that some reasonably reliable laws exist; and also that the biological side is more difficult, more unpredictable, and less developed.

In view of the pressing practical problems in industry, it is not surprising that the applied side was especially active. Very soon after the war, the U.S. OSRD published a *Handbook on Aerosols*. Over twenty-five years later, this very useful handbook was updated and revised by the U.S. Energy Research and Development Administration (ERDA) (Dennis 1976). It is full of tabular information important to anyone with responsibilities for air contamination, measurement and control. In addition, because of the special needs of the AEC contractors to remove the last vestige of toxic particles from waste gas streams, and for their control and measurement, the commission sponsored periodic "Air Cleaning Conferences." The first seventeen of these have been tabulated recently by Burchsted (1981).^(a) Given below is an excerpt from this publication that gives the site and year, and also the publication number for the several conferences.

AEC/ERDA/DOE Nuclear Air Cleaning
Conference Document Numbers

Conference Number	Conference Year	Conference Location	Document Number
1	1951	Boston	No Proceedings
2	1952	Ames	WASH-149
3	1953	Los Alamos	WASH-170
4	1955	Argonne	TID-7513
5	1957	Boston	TID-7551
6	1959	Idaho Falls	TID-7593

15	1978	Boston	CONF-780819
16	1980	San Diego	CONF-801038

The number of aerosol scientists with leanings toward applications in the biological sciences and in industrial hygiene was never large. Even fewer gained expertise also in the field of radioactivity or the handling of radioisotopes. During the war, as we saw, the people who needed the results worked in collaborative groups on the techniques of exposure and measurement. In the postwar

(a) The eighteenth conference was expected to be held in August 1982 in Denver.

(b) Available from the International Atomic Energy Agency (IAEA) as STI-PUB-195.

period, there gradually developed a tendency to have either specific aerosol science sections around the major inhalation projects or to have some experts in aerosol science easily available to the bioscience groups.

The idea of having a specific aerosol section was probably first implemented at Rochester. This became a natural milieu by the presence of a graduate program and academic research opportunities. The long-term uranium experiment (chapter 2) was going ahead, more or less on the old basis, aided greatly by the use of the Wright dust feed (Wright 1950), another idea introduced from England.^(a) Some of the wartime people with aerosol experience were still available (Charles LaBelle, Sidney Laskin, Kenneth Lauterbach, and Robert Wilson, among others), but some were beginning either to scatter to industry, to other universities, or to other duties at Rochester. At about this time, a Ph.D. student in pharmacology, Thomas T. Mercer, who had a knack for quantitative science and a good pair of hands for building equipment, decided he preferred what he had seen in the aerosol work to conventional pharmacology. Toward the end of Mercer's Ph.D. journey, one of the central figures of British Aerosol Science, Dr. C. N. Davies, visited Rochester, gave some seminars, and he and Mercer met. In due course, arrangements were made for Mercer to serve a postdoctoral period with Davies, whose primary work concerned coal dusts and the work of the British Coal Board. On completion, Mercer returned to Rochester to organize one of the first Aerosol Science sections built around a radioactive inhalation program.^(b)

The Aerosol Section, as organized, provides advice to those doing inhalation experiments, but is far from a service organization. Indeed, their focus is on fundamental aspects of the science.^(c) This has led to several modifications of technique in programs at Rochester and elsewhere and attacks on basic problems, such as the role of electrical charge phenomena—especially important, and troublesome—in work with radioactive aerosols. Some of this work will come to our attention as we review the postwar inhalation studies, but for most of it the reader is referred to the literature already cited, and papers in the several aerosol symposia.

Another Rochester Ph.D. student, Otto Raabe, had his interest in aerosol science kindled while in a biophysics program. In due course, he went to the Lovelace Fission Product Inhalation Laboratory to fill the job which Mercer had vacated. There he remained until recently when he moved to the University of California at Davis. He did much work on the *in vitro* solubility and dissolution of particles in simulants of lung fluid (see section IV B). During the interim, between Mercer's departure and Raabe's coming to Lovelace, Robert G. Thomas, a much earlier Rochester graduate with broad interests in the entire

(a) The cascade impactor was the first, as we saw earlier.

(b) The plan nearly came to grief when Mercer, a native of the Pacific Northwest, was enticed to the University of Washington for a while and then went to be the aerosol anchorman at the new Fission Product Inhalation Laboratory at the Lovelace Foundation. However, he eventually returned to Rochester and headed the Aerosol Section for the balance of the period of interest in this book.

(c) For reasons that are not really clear, the excellence of this aerosol group seems to have been appreciated more abroad than in the United States. There have been numerous visiting scientists from Europe in the laboratory from postdoctoral fellowships up to faculty appointments. Several have returned to senior posts in Europe; a few have stayed.

field of pulmonary radiotoxicology, devised many experiments involving aerosol exposure techniques and the importance of particle size in toxicity.

Yet another product of the Rochester program was Robert Phalen, who now presides over important and complex exposure units in the Department of Community and Environmental Medicine at the University of California at Irvine. He also conducts basic aerosol research in the field of air pollution.

The Lovelace aerosol group initially felt the loss of Mercer very keenly (McClellan 1981). The help from Thomas's and Raabe's coming helped at a critical time. They developed a strong and active aerosol group under the supervision of George Kanapilly.^(a) By September 1981, the Aerosol Science group listed nineteen personnel, including six with Ph.D. degrees and one with a Sc.D. Some of these take part, of course, in the development of facilities for inhalation exposures. There is also a section called "Exposure Operations Section" under the Aerosol Science group. This group in toto may be one of the most extensive flowerings of the formally organized Aerosol Science group within an inhalation toxicology program. It has been especially appropriate to this laboratory as it expanded beyond radioactive inhalation problems to very general inhalation toxicology.

At Hanford, the development of aerosol science took a different course, especially in the first two decades after World War II. Radioactive inhalation work began in about the mid-1950s.^(b) There was already a strong program in atmospheric science in another part of the operation under James Fuquay, which included Lyle Schwendiman and Jofu Mishima. For many years, the principal investigator (W. J. Bair, whom we met in chapter 8) and his closest associates (D. H. Willard and L. A. Temple, among others), with help from plant-wide liaisons, devised exposure chambers, aerosol generators, measuring systems, etc. Like many others, they were patterned after existing models in principle but soon assumed special characteristics for the purposes at hand. During the ensuing years, Bair and his group developed a number of important and unique aerosol administration devices, including face masks for dogs, a device by which beagles could inhale radioactive dust as well as smoke cigarettes, and a wide variety of exposure chambers for different purposes. Bruce Stuart, who received his training at Rochester, but in another field, was especially active in some of these developments. Occasionally, someone from the sister department, the section on Radiological Development and Calibrations of the Radiation Protection Operation, would join forces with the biologists sufficiently to become a coauthor (e.g., Swinth) or to prepare independent publications concerning aerosol problems (e.g., Healy, Roesch, Anderson).

On the occasion of delivering a series of lectures in Japan in 1969, Bair (1970) reviewed and pictured the many types of exposure rigs they had devised.

By the 1970s, the annual reports from what had now become the Biology Department of PNL, which is operated by Battelle Memorial Institute, cited work in a section termed, "Development of Aerosol Exposure and Analytical Techniques" with W. C. Cannon listed as "Person in Charge." D. K. Craig was part of this group and later was responsible for Battelle's earliest approach to a specific aerosol section. Craig received a Ph.D. at Rochester with a thesis in

(a) They do train bioaerosol scientists at places other than Rochester! Kanapilly was trained at Wayne State University.

(b) The development of the Hanford/Pacific Northwest Laboratory (PNL) inhalation program will be reviewed in section IV A.

"pure" aerosol science (see Craig 1962). He was originally a research officer for the South African Atomic Energy Board, but elected to return to the United States a few years after completion of his Ph.D. Fredrick Cross, still another Rochester graduate, whom we met in connection with radon problems in chapter 3, was close by in the sister group. It might be said that this organization was a counterpart of the specified aerosol sections at Lovelace and Rochester. Certainly they engaged in fundamental aerosol research as well as taking part in the inhalation toxicology program. However, it seems not to have been quite so formalized as some of the other groups. After Craig left to take up duties at Headquarters in Washington, Owen R. Moss, another University of Rochester graduate, joined Cannon and others in the group. Moss had had considerable experience in aerosol work.

At Los Alamos, the Industrial Hygiene group under Harry Schulte represented the core of aerosol science. Only for some specific problems (see section V A, and work around the field tests) did the biology and medicine groups get very much involved with aerosol research.

In New York at the Health and Safety Laboratory (HASL), which operated under AEC and ERDA, and now as the Environmental Measurements Laboratory under the Department of Energy (DOE), we see yet another way in which aerosol science was folded into pulmonary radiotoxicology. This laboratory started as part of the New York Operations Office and had special responsibilities for uranium dust problems, even in the Manhattan Project days. Over the years, it became as much involved with environmental as with occupational problems. It was a center for measurements of fallout throughout and after both the Continental and Pacific atmospheric testing programs, as we will see in some detail in chapter 12. We have already seen (chapter 3) something of its involvement in radon measurements and the uranium miner problems. The laboratory devoted much of its effort to the development of methods and instrumentation for the assessment of levels and hazard and has provided definitive documents on natural background radiation. In a sense, the Health and Safety Laboratory provided a base in aerosol science as well as in other pertinent methodological and instrumental areas to the whole of AEC and its successor agencies much as the specific sections within laboratories served specific laboratory programs.^(a)

The Institute of Environmental Medicine at New York University (NYU) has had a strong general aerosol science component in its operations throughout its existence. With this we associate names like Merrill Eisenbud, who came to NYU from the precursor of HASL with much experience in the problems of inhalation of uranium and beryllium dusts; McD. Edward Wrenn, a home-grown product; Sidney Laskin, who went to NYU from Rochester; Norton Nelson, the Institute's very broad-gauged director; Bernard Altshuler, an old pro for aerosols and modeling; and, in later years, Naomi Harley and B. S. Pasternak and others whose work we have seen or will soon meet. This laboratory, much like Battelle's, operated with most of the aerosol experts as part of the team for a given experiment, and no separate aerosol section.

Many other laboratories, e.g., in the Graduate School of Public Health at the University of Pittsburgh, the U.S. Public Health Service Laboratories in Cincinnati, and others were engaged in aerosol science activities; a few of which

(a) I am greatly indebted to Dr. John H. Harley, recently retired director of the laboratory, for a capsule history and selected publications pertinent to radiation toxicology (Harley 1981). We will quote these in proper context.

e.g., the work of Cember at Pittsburgh) were oriented toward radioactive inhalation problems. We will review these later. The reader can find their more general contributions in some of the monographs mentioned earlier, and in the journal literature of industrial hygiene and occupational medicine.

2. Generalization of Results in Aerosol Science

From our review of pulmonary radiotoxicology, a few items of essentially universal applicability from the work in aerosol science and related areas should be summarized.

a. Role of Particle Size in Deposition

The advances in methodology in the postwar years permitted determination of pulmonary deposition over a very wide range of particle sizes. The region of ultra-small particles is only now being addressed by Stahlhofen and colleagues. From essentially no deposition above about $20\ \mu$ activity median aerodynamic diameter (AMAD), the pulmonary deposition reaches a maximum at between $1\ \mu$ and $2\ \mu$, decreases to a minimum in the region around $0.5\ \mu$, and then appears to rise slowly in the region where Brownian motion is important.

The above is a generalization for alveolar deposition. Deposition in the nasopharyngeal region is skewed sharply toward the larger sizes. The tracheo-bronchial region shows much less deposition than either nasopharyngeal or pulmonary regions, but there is a distinct rise in the deposition fraction below $0.05\ \mu$ mass median diameter (MMD). These relationships apply equally well to nonradioactive or to radioactive aerosols.

Detailed discussions and diagrams can be found in the report of the Task Group on Lung Dynamics of the International Commission on Radiological Protection (TGLD 1966), reviews by Stuart (1973, 1976), ICRP 1980, and the monographs already cited. A particularly clear exposition of the several physical forces (gravitational settling, inertial impaction, Brownian motion, coagulation, electrical charge, condensation, thermal effects, and concentration) can be found in a review by Morrow (1960). Actual experiments are legion. We will cite two: an early set by Brown et al. (1950) at Pittsburgh and the Mellon Institute and one in man by Morrow et al. (1958) at Rochester.

A summary of the respiratory tract deposition models in animals and man was prepared recently by the Lovelace group (Yeh 1980) and is being examined in detail by both the ICRP and the National Council on Radiation Protection and Measurements (NCRP).

b. Practices

The above generalizations did much to reorient operations in practical air sampling. The importance of selective size sampling, especially to distinguish respirable dust, was appreciated. Many devices for routine sampling that could make that distinction were developed. The philosophy behind this is addressed in some depth by Morrow (1964).

c. Role of Physiological Factors in Deposition

While the biological factors were sometimes a source of irritation to the aerosol scientists, who were usually physical-science oriented, they were inevitably present in the experiments. Parameters like tidal volume, respiratory rate, ventilation rate as influenced by the work rate of the subject, had to be separated out and their importance evaluated. It turned out that ventilation rate and tidal

volume could easily have as much influence on deposition as particle size. Thus, the deposition curves form an envelope when plotted against particle size—the envelope reflecting the influence of physiological factors, as well as the range of variability.

d. Retention and Clearance

In our review of the wartime work, we saw the first indication that particle size could affect clearance and ultimate toxicity as well as deposition. In the postwar work, many other parameters and processes entered the picture. The basic findings of the war years were not controverted. However, the new work showed that the picture was not as simple as the early Rochester work predicted. For example, Boecker (1962) found that thorium chloride remained in the lung longer the larger the particle size. (The difference could amount to a factor of three.) Similar results were reported from Hanford with plutonium. However, retention in the *whole body* (using whole-body counting methods) showed just the opposite relation. Part of this discrepancy rests on amounts cleared from the lung early-on versus later. A thorough treatment of the influence of aerosol properties on distribution, retention, and excretion is given in papers by Thomas (1964a,b; Thomas et al. 1973) using aerosols of antimony, plutonium, polonium, niobium, uranium, and thorium. Particle size has a marked influence on subsequent behavior, but it can be overshadowed by differences in chemical form.

Interestingly, and despite the intrusion of many other parameters, Parsont, Holley, and Burnett (1972) return, in modern modeling garb, to the earlier work on particle size and point out how the lung dose decreases for small particles ($\leq 1 \mu\text{m}$), while the dose to other internal organs increases correspondingly because of more rapid removal of the smaller particles from lung to other tissues. They point out that this may change the critical organ from lung to some other organ or tissue (e.g., liver or kidney) and admonish the ICRP to incorporate these considerations in the official lung model.^(a)

e. Mechanisms of Lung Clearance

The work on mechanisms of lung clearance is more in the domain of biomedical scientists than of aerosol scientists. However, the teamwork approach soon involved the latter in this largely biological and biochemical enterprise. A review paper by L. J. Casarett (1960) sets forth the primary processes, i.e., movement by ciliated epithelium, phagocytosis, lymphatic absorption, and solubilization.^(b) The aerosol people got especially involved in the latter.

Rather sophisticated kinetic analyses have been made of the clearance of inhaled particles (Morrow 1977). The presence of many patterns has become obvious from the prodigious assembly of experiments on plutonium and related actinides gathered and presented by an ICRP task group chaired by W. J. Bair (ICRP 1980) and from the summary in the same volume for experiments on beta-gamma emitters. These do not always yield to mechanistic analysis, but approximations as to what is going on in vivo are reasonably satisfying.

f. Special Considerations for Radioactive Aerosols

The work in aerosol science found many ways that the presence of radioactivity modifies some of the generalizations. For example, the electrical-charge

(a) The model does provide for calculations at other than the standard particle size.

(b) We would now include diapedesis via lymphocytes or even of naked particles through the alveolar wall in this listing.

characteristics of the radioactive aerosol may differ from the nonradioactive one simply because of the ionizations produced by the decaying atoms.

A most important consideration is the relation between mass and toxicity. For most chemical aerosols, the toxicity is related to mass unless surface area characteristics play a definitive role. Thus, the curves for deposition as a function of particle size reflect ultimate toxicity so long as we are not dealing with vector aerosols.^(a)

The aerosols of radioactive materials are almost always of the vector type, i.e., the activity becomes attached to particles of nonradioactive dust. As Stannard pointed out (1959), quoting work by Mercer and Wilkening, radioactivity does not necessarily attach to the vector aerosol particles in proportion to their mass. In fact, both natural radioactivity and artificially produced radioactive aerosols may have a disproportionate amount of their activity associated with the smaller particle sizes. Thus, it might be very wrong to predict hazard from the behavior of the vector. The maximum activity may occur where the mass deposition is quite low.

To avoid this potentially dangerous mistake, it has become customary to characterize radioactive aerosols in terms of activity, i.e., the AMAD. This is especially important for aerosols of substances of high specific activity, less important for substances of low specific activity like natural uranium.^(b)

Thus, we need to know even more about a radioactive aerosol than one whose effect is largely due to chemical toxicity (Stannard and Morrow 1956).

g. Monodisperse Aerosols

It has become possible to prepare monodisperse aerosols of various particle sizes. These are very convenient when an experiment is desired without the complications of a range of particle sizes. The generators for these aerosols are described by Mercer (1973) among others. The methodology includes atomization of latex particles, which can be obtained in quite uniform sizes (more in connection with Lovelace).

h. Polydisperse Aerosols

The polydisperse aerosol still occupies a key position. It should, since this is the form in which "real-life" exposures take place. A conscious decision was made for the centers, to be described in the next section, to use polydisperse aerosols at Hanford and at most of the other centers with definitive work on the monodisperse variety centered at Lovelace. The designs of Dautrebande (1962); Lauterbach, Hayes, and Coelho (1956); and a modification termed the Lovelace generator are the most generally used (Mercer, Tillery, and Chow 1968). Diagrams of these are in Mercer, Tillery, and Chow (1968); Bair (1970); and the original publications.

(a) Modern work in chemical toxicology and air pollution indicates that vector aerosols may be more common than suspected.

(b) This contribution alone is probably enough to justify the emphasis on aerosol science in the inhalation programs. Incidentally, it seems to have come in part from examination of radon daughter aerosols (chapter 3) and the wide variations in specific activity seen in fallout particles (Williamson 1957; Farlow and Schell 1957).

C. The Naval Radiological Defense Laboratory

The origin and mission of the Naval Radiological Defense Laboratory (NRDL), which started in the late 1940s, are described in chapters 12 and 13. As a part of this laboratory's general examination of the consequences of radioactive fallout, it carried out a few inhalation experiments, which were done primarily by Dr. Stanton Cohn and his colleagues, especially J. K. Gong. Mice were exposed by the nose-only procedure to fallout simulant aerosols under different conditions of solubility. For the dry particle aerosol, uranium was irradiated by neutrons in the Materials Testing Reactor at Idaho Falls, the resultant mixed fission products were dissolved in acid and then added to a solution of ambrose clay loam (fancy dirt). The average diameter of the dirt particles was $1\ \mu$ to $5\ \mu$, and the fission products were adsorbed on their surfaces. The exposures took place two days after removal of the irradiated uranium from the reactor. Therefore, the very short-lived and gaseous fission products played no role in this experiment.

Cohn et al. (1957a) reported phased clearance of the inhaled material from the lung, largely to the gastrointestinal tract, but with some going to liver, skeleton, thyroid, and head. A separate measurement was made of absorption from the gastrointestinal tract, and it was found to be significant (i.e., enough to account for one-half of the tissue burdens) and considerably more rapid than absorption from the respiratory tract. A simulant in ionic form, reported upon earlier (Cohn et al. 1955), and an ionic-mud slurry were compared to the dry particle simulant. The results were interesting and somewhat unexpected. The highest tissue activities expressed as a ratio to the activity in the respiratory tract occurred after inhalation of the dry particles and the lowest after inhalation of the ionic simulant. The loss rates from the tissues suggest that a few components of the mixtures predominated so that the activity in tissues fell more or less exponentially with time. The highest dose per gram of tissue was to the thyroid in the early hours. Over an extended period, bone would receive the largest integrated dose. Both of these findings are premonitory to simplifications of the dosimetry adopted in the later work with fallout.

While the animals were exposed only to the aerosol, calculations were made of the external radiation dose that might have occurred had there been submersion in a cloud of the same composition. With 2π geometry, the external dose would exceed the internal by a factor of eight, but the internal dose rate would fall off more slowly and be of importance at later times after exposure.

In a companion report, Cohn et al. (1957b) reported on the metabolism of inhaled aerosols of radiostrontium and radiolanthanum. Results with strontium were similar to those already described from the war work, except that bone took up activity so rapidly that it exceeded lung even 0.5 hr after exposure. (And this was for a dry particle aerosol!) With a liquid aerosol, body and bone absorption was even greater. Lanthanum, on the other hand, penetrated to internal tissues hardly at all. This sharp contrast in behavior of these two radionuclides was indicated by the wartime work, but was especially striking in the NRDL experiments.

Except for some work on radon, discussed in chapter 3, these studies, i.e., mixed fission products in a sea-water aerosol, in a mud slurry, and as dry particles, and the work with strontium and lanthanum constitute all of the actual inhalation experiments done at NRDL. However, the laboratory played a very active role in general analyses of fallout problems in the several Congressional hearings we will look at in chapter 12. At one of them, Stanton Cohn (1959) evaluated the hazard for inhaled radioactive fallout. He concluded that the

radiation dose from internal sources would be quite small compared to the external dose. Iodine in the thyroid was the only potential exception.

IV. Maturation: The Genesis of Centers for Pulmonary Radiotoxicology^(a)

A. Hanford/Pacific Northwest Laboratory

The salient features of the development of the Biology Operation at Hanford under General Electric Company management were set forth in chapter 8. The major biomedical programs with radioactive materials, except those involving pulmonary radiotoxicology, were also described there. However, the omission of the inhalation toxicology work was a major one, for in the postwar years Hanford and its successor, PNL, became a major center for such work. Indeed, for many years, until the Lovelace program was fully developed, it preempted the entire field in terms of facilities, personnel, and commitment to inhalation problems.

1. The Early Phases

The inhalation program at Hanford seems to have started by placing a few mice in the atmosphere of a chemical processing plant expected to contain radioactive particles. It gained urgency with the discovery of "hot particles" of ruthenium and other radioelements in the plant environs and the known releases of radioiodine vapors from the stacks.

A more formal effort was organized in the early 1950s under the title "Pharmacology Operation." Dr. Ralph Wager headed it with collaboration especially from D. H. Willard, L. A. Temple, V. Smith, and N. L. Dockum. The work was done in a Quonset hut not far from the facilities developed for the Biology Operation in the so-called 100-F Area, thirty miles north of Richland along the Columbia River. An old photograph of this Quonset hut facility is shown as figure 9.12.

The program concentrated on introducing the relevant radioelements to animals by the technique of intratracheal instillation. There was not time to wait for the development of safe and effective means of producing aerosols of radioactive materials with good control of dosage.

Wager and his colleagues produced the first clear demonstration of lung cancer from plutonium—squamous cell carcinomas in mice that had received $\text{Pu}(\text{OH})_4$ or PuO_2 particles from eleven to seventeen months previously. This was reported in the Biology Research Annual Report for 1955 (Wager et al. 1956). Ruthenium-106 particles given in the same manner produced only necrosis and fibrosis of the lung. The squamous cell carcinomas^(b) appeared in three of ten mice examined one year after intratracheal injection of 0.06 μCi PuO_2 . Autoradiography demonstrated the association of these and other lesions in the lung with the presence of radioactive particles. This was a first for plutonium, to be put beside the first for cerium reported by Lisco and Finkel (1949).

(a) The several centers are introduced in the approximate order of their entry into the field or their maturity at the beginning of the post-World-War-II period.

(b) Just to be sure, the diagnosis was confirmed by the dean of experimental radiation pathologists and director of the AEC Division of Biology and Medicine, Dr. Shields Warren.

FIGURE 9.12. The original hutment for the "Pharmacology Operation" where the Hanford pulmonary radiotoxicology program started. (Photo courtesy of Pacific Northwest Laboratory.)

Wager et al. describe the role of phagocytes, the aggregation of plutonium in the lung, and other phenomena in the reports for 1954 and 1955. This includes a method for quantitative autoradiography of ^{106}Ru particles in lung tissue (Dockum and Healy 1955).

2. A Commitment is Made

Ralph Wager died unexpectedly in 1956 leaving the fledgling inhalation program at loose ends. A couple of years previously, Dr. William J. Bair had come to Hanford with a Ph.D. in radiation biology from the University of Rochester.^(a) He came to Hanford to continue work on radiation effects in yeast and other microorganisms with Dr. Frank Hungate. However, he had been through the Rochester program with a thorough drilling in the industrial hygiene course by both taking it and helping to teach it. This was enough to give the Hanford people confidence that he could take over and develop their inhalation toxicology operation (officially still "Pharmacology Operation"). Bill Bair was amazed when he was requested to do so but accepted nevertheless, threw his considerable energies into the operation, and quickly developed an effective and creative organization. The problems posed by General Electric and the past experiences of the plant were largely practical, and the Pharmacology Operation

(a) Dr. Bair was the first student in the world to receive a Ph.D. in the new and growing discipline of radiation biology. He was also the first Ph.D. student to do thesis research under the general supervision of this author. His career and contributions make me especially proud to have had an opportunity to help him get started.

tackled these with dispatch. Development of techniques for aerosolizing radioactive materials progressed rapidly. By 1958, reports were appearing that involved administration of aerosols of radioactive particles of ^{106}Ru , ^{239}Pu , ^{90}Sr , and ^{131}I (Bair et al. 1958; Willard and Bair 1958). The first paper is a summary review prepared for the first International Congress on Radiation Research held at Burlington, Vermont. It gives little experimental detail. However, such detail can be found in the Japanese lectures already cited (Bair 1970).

Retention, distribution, and excretion were compared in mice with unexpected results. For example, whole-body retention of plutonium, ruthenium, and strontium were approximately the same, whereas pulmonary retention of strontium was much shorter than for plutonium and ruthenium. A peculiarity of these experiments was the considerable translocation of the inhaled particles to ovary. This was sufficient to raise the question of using ovary as critical organ in computing allowable air concentrations for it. The observation does not seem to have held up consistently in later work at Hanford, however, for the point is not reiterated.

It was too early to expect long-term effects in these animals, but the authors fell back on further effects appearing in the animals that had received intratracheal instillations. Malignant lung tumors appeared in the animals receiving ruthenium dioxide as well as those receiving plutonium. Thus, the roster of radioactive elements producing lung tumors was steadily increasing.

The Willard and Bair work (1958) contains some key findings relevant to all of pulmonary radiotoxicology, as well as to the long-standing questions of inhaled iodine. They compared in mice the biological fate of ^{131}I inhaled as a vapor with an insoluble particulate, silver iodide (Ag^{131}I). The latter is not only the most insoluble compound of iodine (in water) but among the more insoluble substances known. The idea was that the vapor would be rapidly absorbed and excreted and some would be deposited in the thyroid, while the Ag^{131}I would hang up in the lung and provide a base for studying the effects of ^{131}I in the lung. The results were a total surprise. While the percent deposition of the vapor was far ahead of the silver salt (70% versus 12%) both left the lung rapidly and appeared in blood, liver, spleen, kidney, adrenals, and, of course, thyroid. The retention half-time in lung was so similar for the two forms that it was decided it represented only blood retention time.

The comparative deposition and kinetics of retention of these two forms of inhaled iodine are shown in figure 9.13, taken from the Hanford report.

Clearly, the differences in transport are far less marked than the differences predicted by the water solubility of the two substances. This led the authors to caution all workers in inhalation toxicology of the pitfalls of basing predictions or calculations of Maximum Permissible Concentrations on solubility of a compound in pure substances rather than in tissue fluids. This has been going on ever since. Much aerosol work has addressed the problem as discussed in other portions of this chapter. We are still being surprised by the unique properties of body fluids.

Since the generator for iodine vapor and the dry box are of an early design, they are pictured below as figure 9.14A and B.

This work was published in the open literature three years later (Willard and Bair 1961) with the addition of experiments on sheep. There were problems with the Ag^{131}I aerosol in the experiment with sheep, but by turning to oral, subcutaneous, and intraperitoneal routes, they got a reasonable comparison of vapor and particles in the sheep. Again, all major metabolic parameters were similar for the two forms, even among the several routes of administration.

FIGURE 9.13. Relative distribution of I^{131} in mouse tissues. (Redrawn from Willard and Bair 1958.)

FIGURE 9.14A. Iodine-131 vapor generator. (Redrawn from Willard and Bair 1958.)

FIGURE 9.14B. Mouse exposure chamber within a glove box for exposure to iodine. (From Willard and Bair 1961.)

The conclusions were that iodine will usually be rapidly absorbed and transported, quickly excreted, temporarily deposited in some soft tissues, but primarily in the thyroid, which is the critical tissue under all conditions. Further work was done at Hanford on inhaled iodine, but it is more pertinent to reactor problems, which we will consider in the next chapter.

Other reports during the first few years of the Hanford inhalation operation concerned the pharmacokinetics of ruthenium particles and plutonium oxide given intratracheally (Willard, Temple, and Bair 1957; Bair 1958). It is interesting to find our old friend, the power function of time, which we had much occasion to discuss in connection with radium, turning up in the whole-body turnover of ^{106}Ru in mice, but with two phases rather than a single line and the more rapid component occurring later rather than earlier. This somewhat unique relationship is shown in figure 9.15.

FIGURE 9.15. Whole body turnover of Ru^{106} in mice. (Redrawn from Willard, Temple, and Bair 1957.)

Each annual report brought expanded and more sophisticated discussions in pulmonary radiotoxicology. In addition to the experimental reports, Bair lost no opportunity to prepare definitive reviews of the entire field and present them at the growing number of symposia being held. Samples of these are the International Congress on Radiation Research in 1958 (Bair et al. 1958), the review at the symposium on Radioisotopes in the Biosphere (Bair 1960), the one on Inhaled Particles and Vapors (Bair 1961), the IAEA meeting on Diagnosis and Treatment of Radioactive Poisoning (Bair, Tombropoulos, and Park 1962), and the IAEA symposium on Radiological Health in Mining and Milling of Nuclear Materials (Bair et al. 1964).

Thus, within five years, not only was Hanford committed fully to an ongoing program in pulmonary radiotoxicology, but Bill Bair and his staff^(a) had made a sophisticated and systematic start on many of the problems that had been hanging fire since the early days of the Manhattan District. The technical problems of producing radioactive aerosols safely, reproducibly, and in sufficient quantity for effects as well as tracer-level work were being solved and the ground prepared for long-term studies.^(b)

Naturally, the group outgrew the Quonset hut facility in short order. Sprawling one-story buildings multiplied adjacent to the area used for the sheep work discussed in chapter 8. These could contain exposure chambers, animal test and care facilities, and even an office or two. However, conference and library facilities were still in the relatively close (except on the occasions of Richland's winter fogs) facilities in the Biology Building. All were in the 100-F Area where they had started. There was room to sprawl and no worry about space for animals. But it was not an environment conducive to lunch-table philosophical conversations, for the need to get into and out of protective clothing and the rule of having no food within any potentially radioactive area, restricted academic informality.

A photograph of this facility taken near the zenith of the development in the 100-F Area is given as figure 9.16.

3. Plutonium Takes Over, Almost

Whereas the inhalation program from its inception to the early 1960s was somewhat diversified in that a number of different elements were under study, the next decade saw a major portion of the effort concentrated on the inhalation toxicology of plutonium.

The wartime mission of Hanford was the production and purification of plutonium. The hazard of ultimate concern was the long-term toxicity of inhaled plutonium. With additional laboratories at the animal farm completed, the

(a) Among the new staff that joined the inhalation program in these years were two more products of the University of Rochester: D. K. Craig, whom we met in the section on aerosol science, and Bruce O. Stuart. Stuart, like Bair, did his research under the general guidance of this author, again in fundamental cellular radiobiology. He, too, had taken and helped teach the industrial hygiene and toxicology course. It began to appear that going through the Rochester program was enough to qualify any student for work in pulmonary radiotoxicology and that the thesis subject could be in quite another area without detracting from the potential for such work!

(b) In contrast to the earlier efforts with uranium at Rochester, which involved materials of low specific activity, this work involved materials with much greater hazard potential, particularly for work involving large numbers of animals.

FIGURE 9.16. Photograph of 100-F Area inhalation toxicology facilities at Hanford. (Photo courtesy of Pacific Northwest Laboratory.)

major problems of handling plutonium aerosols and its measurement *in vivo* overcome, the problem could be attacked broadside. First, the acute toxicity; influence of chemical form; and particle size, retention, distribution, and excretion needed study or rechecking. Then a long-term experiment could be begun. (Actually some of these efforts went in parallel, of course.) Mechanisms could get more attention.

Diversification increased rather than decreased in this period because the plutonium problem developed in its own right into several subproblems, and new aspects of its use caused considerable pressure from Headquarters to embark on new semiapplied pathways. Also, the U.S. Air Force became quite interested and actually supported the first dog studies.

One of these was the "Space Nuclear Systems" work, which will be discussed in section V C. Another concerned some medical applications extending to americium and californium (Seaborg 1973). For many years, the inhalation toxicology group reported some of its work regularly under the title "Space Nuclear Systems Studies." The devices were a joint development of AEC, the National Aeronautics and Space Administration, and the Department of Defense, but biomedical aspects resided in AEC.

In due course, experimental work on the uranium mining problems, discussed in chapter 3, came to Hanford with emphasis on possible additive or synergistic effects of cigarette smoke, uranium ore dust, and diesel exhaust fumes.

Threading through all of this work were studies aimed primarily at mechanisms.

Some of the attempts at therapeutic removal of deposited radionuclides alluded to in chapter 8 and slated for details in chapter 19 were directed at removal of radioisotopes, particularly plutonium, from the lung.

Obviously, the program was growing quite beyond the times when Bair and a few colleagues and technical assistants could handle it all. A degree of specialization and compartmentalization had to develop. Yet, to the credit of those responsible, most of the senior staff had a finger in several of the projects and could at the same time develop their own interests. We will review very briefly below what went on in these various areas, who was primarily concerned, and the highlights of the results. Since the literature is very complete and largely accessible, excessive details will be avoided.

Before attempting this review, we should pause to note the 1964 Hanford symposium on Inhaled Radioactive Particles and Gases. An indication of the rapid maturation of the Hanford inhalation program was their sponsorship of this full-dress symposium on 4-6 May 1964.^(a) There were over 160 visiting scientists from nine countries and 180 Hanford scientists participating. Nearly every major laboratory doing pulmonary radiotoxicology was represented, and papers were presented from most. About a fifth of the papers were from the Hanford program, a fine showing for an enterprise begun less than eight years before. The symposium was published in *Health Physics* as Volume 10, Number 12 in December 1964 (see Hanford symposium listings in chapter 8).

- a. **Long-term Studies with $^{239}\text{PuO}_2$** ^(b) (W. J. Bair, J. F. Park, B. O. Stuart, W. J. Clarke, C. L. Sanders, D. K. Craig, P. L. Hackett, E. B. Howard, H. A. Ragan, and others.)

The most extensive inhalation studies with dogs used $^{239}\text{PuO}_2$ prepared by calcining the oxalate at about 350°C.^(c) Particle size was 0.3 to 0.5 μm count median diameter (CMD), about 3 μm MMD. About one hundred dogs were exposed to from less than 1 μCi to 50 μCi . The latter caused early acute effects. The basic experimental protocol had four phases:

1. pre-exposure phase—training of dogs for the aerosol exposure, complete physical examination, establishment of physiological base lines, and acclimatization to the metabolism cages
2. exposure phase—a single exposure lasting from ten minutes to two hours; respiratory parameters measured
3. metabolism-cage phase—for varying periods for collection of excreta, plus periodic measurements of other parameters
4. sacrifice/euthanasia phase—metabolism animals killed on a predetermined schedule or when toxicity made euthanasia advisable. Other animals were set aside for long-term observations. Hematology, roentgenography, and many other interim procedures were applied regularly. Plutonium retention was generally logarithmic to time over the long haul, and loss, once the rapid phase was over, was slow. Some organs gradually accumulated plutonium but took from two to four years to approach significant translocated amounts. Liver and bone continued to increase as fraction of the body

(a) This was the third Hanford symposium; see chapter 8.

(b) This program was started when the General Electric Company was still operating Hanford, but it ran far into the era of Battelle sponsorship. Indeed, it is still under way. The transition took place in 1965.

(c) Other forms were compared. This one showed greatest accumulation in the tracheo-bronchial lymph nodes and relatively rapid clearance from the lung.

burden as long as tissue content measurements continued. These were extrapolated to as long as fifteen to twenty years by a computerized simulation model.

The model and the extrapolated tissue contents are shown in figure 9.17A and B.

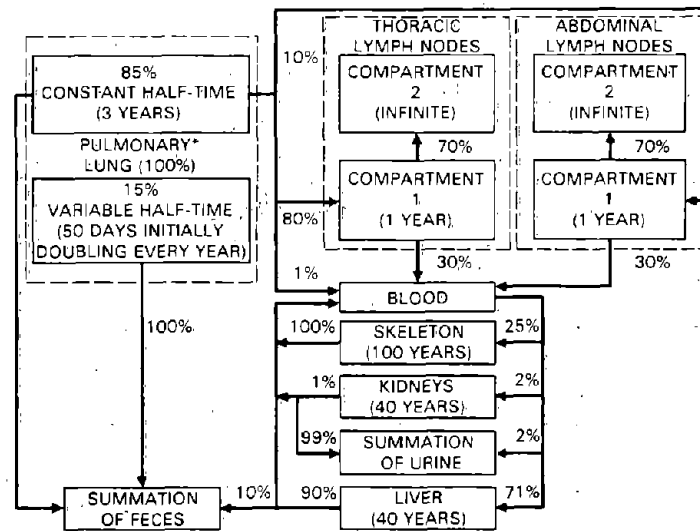

FIGURE 9.17A. Long-term dynamic simulation of inhaled $^{239}\text{PuO}_2$ (half-times in parentheses). (Redrawn from Stuart, Dionne, and Bair 1971.)

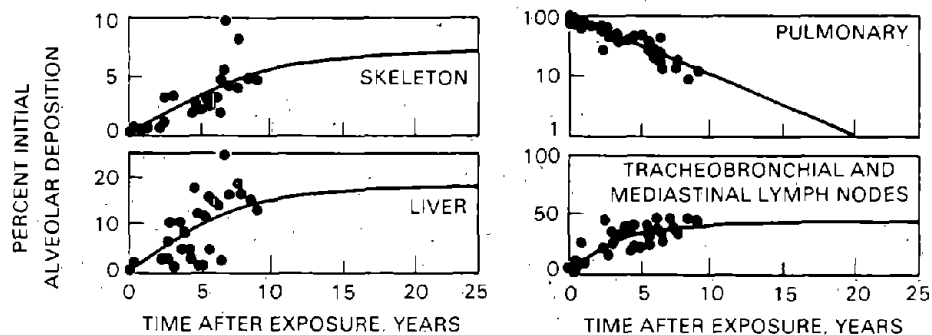

FIGURE 9.17B. Long-term tissue burdens of plutonium after inhalation of $^{239}\text{PuO}_2$. Points from experimental data, lines from model shown in part A (Modified slightly from Stuart, Dionne, and Bair 1971.)

The effects of inhaled plutonium vary with dose, of course, and there is much overlap among categories of pathology. A representation used by the Battelle group on several occasions is given in figure 9.18.

FIGURE 9.18. Observed biological effects of inhaled plutonium. (Redrawn from Bair 1974; also ICRP 1980, figure 9, p. 37. Reprinted with permission of Pergamon Press, Ltd., Elmsford, New York, copyright 1974.)

Translated to initial deposition in the pulmonary compartment of the lung, it appears that acute death can occur in the range from $10 \mu\text{Ci/g}$ to approximately $10^{-1} \mu\text{Ci/g}$, subacute death in the range from $3 \times 10^{-1} \mu\text{Ci/g}$ lung to $3 \times 10^{-2} \mu\text{Ci/g}$, and carcinogenic death in the range from $3 \times 10^{-2} \mu\text{Ci/g}$ lung to $3 \times 10^{-3} \mu\text{Ci/g}$ lung. (a)

A somewhat different relationship, which shows also the effect on survival time, has been presented by Bair and his colleagues on several occasions. An example, taken from Bair's lecture series in Japan, is shown as figure 9.19. Here the lowest effective dose is about 2 nCi/g lung at death.

FIGURE 9.19. Relationship between quantity of ^{239}Pu in lung at death and survival time of dogs. (Redrawn from Bair 1970.)

(a) The lower figure of the range may not be a minimum.

Numerous dose-response relationships have been drawn as this long-term experiment unfolded. These relationships are expanded upon in depth in the ICRP publication, *Biological Effects of Inhaled Radionuclides* (ICRP 1980). Here the graphs include not only Hanford and other U.S. data (including PNL and Lovelace data on hamsters), but work from France and the Soviet Union on rats. A few points fall squarely on the abscissa (i.e., no effect). However, this work goes well beyond the period of our present interest.

Bair (1970) calculated the lung burden that was unlikely to produce either cardiopulmonary insufficiency or lung tumor as less than 0.5 nCi/g lung.

b. Influence of Particle Size (Matsusaka, Park, Willard, Bair)

A concise summary of the beagle experiments as of the early seventies is given by Park, Bair, and Busch (1972).

Despite the backlog of information from industrial dust exposures and other radioactive isotope inhalation work, it was necessary to check out influences of particle size in plutonium aerosols under the conditions of these experiments. Plutonium was hardly an ordinary industrial dust.

The effects of particle size on deposition and clearance were found to be broadly consonant with the behavior predicted by the uranium experiments at Rochester. Deposition showed an unexpectedly large difference between two fairly similar aerosols (Bair and Willard 1961). Clearance from the lung was much more rapid and complete for an aerosol with mass median diameter of $0.65\ \mu$ (0.086 CMD) in contrast to either $3.3\ \mu$ MMD or $4.3\ \mu$ MMD, but translocation to other tissues was not uniformly affected. Both PuO_2 and PuHO_3 were used, and the results were surprisingly comparable.

Very complete analyses were made of excretion kinetics. The results are best seen in Bair's lectures in Japan (Bair 1970). On the whole, the predictions of earlier work were realized.

Some work was done with ^{238}Pu as well as ^{239}Pu . Unexpected differences were found, but in this particular work the radiation dose from the ^{238}Pu isotope was quite high and may have complicated the results.

c. Effect of Chemical Form (Dilley, Park, Stuart, Willard, Bair)

Radioisotope toxicology has, in general, needed to concern itself less with the nature of the compound than counterpart work in chemical toxicology. Some special situations apply to plutonium. It was known that plutonium encountered occupationally or in the environment might have been through one of several processes, even if it was nominally PuO_2 , e.g., calcining of the oxalate or metal at different temperatures. Or, different compounds might be present, e.g., PuF_4 and $\text{Pu}(\text{NO}_3)_4$. The different treatments and their effects are described by Bair and Park (1968). A sample of the findings is shown in figure 9.20.

It is clear that: (1) the half-times for PuF_4 and $\text{Pu}(\text{NO}_3)_4$ in the whole body are distinctly shorter than for the "less soluble" PuO_2 , even at smaller particle sizes; (2) ^{238}Pu appears to clear more rapidly than ^{239}Pu , but this may have been a particle-size effect; and (3) differences in chemical form of PuO_2 make considerable difference in retention. Indeed, the differences in chemical form can override differences in particle size. Effects of similar magnitude apply to translocation from lung and behavior in tissues. Autoradiography demonstrated differences in the size and location of the "stars." However, this effort, which was extensive, is too specialized to warrant further exposition here. Suffice it to say that this work alerted all concerned with the evaluation of hazards to the fact

FIGURE 9.20. Summary—whole-body retention half-times for inhaled plutonium in dogs. (Redrawn from Bair 1970.)

that it was necessary to know in some depth the origin of any plutonium available for inhalation before quantitatively reliable evaluations could be made. Also, it pointed up possible explanations for “aberrant” and puzzlingly inconsistent results of the past.

The basic biomedical fact that the organism can distinguish between and handle differently particles of apparently the same size distribution but subtly different in physicochemical composition bespeaks the need for further sophisticated experimentation at the basic level.

d. Plutonium-238

Even before the advent of Systems for Nuclear Auxiliary Power (SNAP) devices (see section V C) and of microspheres of ^{238}Pu , there were indications that the shorter-lived isotope (86.4 yr for ^{238}Pu versus 24,390 yr for ^{239}Pu) behaved differently in vivo. It seemed to be more transportable, aggregates disintegrated spontaneously, and even ultrafilterability of the particles was different and changed with time.

The work on SNAP devices at Battelle, supported in part by the Air Force, involved characterizing the behavior of the ^{238}Pu microspheres, particularly when crushed in simulation of their breakdown in a re-entry incident, and generally comparing the biomedical problems of ^{238}Pu and ^{239}Pu . The results showed that a simple scaling factor based on half-life and specific activity would not predict behavior or toxicity on inhalation.

Stuart (1970) reported that, while the basic pattern of movement from lung to skeleton in rats and to lymph nodes and liver in dogs was not different for ^{238}Pu , there was more ^{238}Pu in the skeleton and in the liver in the rat. The magnitude of the differences is considerable, as shown in table 9.7A and B, modified by D. M. Taylor from Stuart's work.

TABLE 9.7A. Tissue Distribution of ^{239}Pu in Rats After Inhalation of $^{239}\text{PuO}_2$ (percent of body burden at death)

Rat No.	Days After Exposure	Skeleton	Liver	Spleen	Lungs	Tracheobronchial Lymph Nodes

Toxicity studies did not indicate differences beyond those expected from the 282-fold difference in specific activities ($6.12 \times 10^{-2} \mu\text{Ci/g}$ for ^{239}Pu versus 17.4 Ci/g for ^{238}Pu). At one of the numerous SNAP-SNPO meetings held in Washington, Bair (1967) gave acute mortality data for $^{238}\text{PuO}_2$ and $^{239}\text{PuO}_2$ in rats and dogs (see also Park, Howard, and Bair 1970). On a microcurie basis, the two isotopes were about equally effective. Published papers (Stuart et al. 1968; Park et al. 1970) confirmed these findings. There were, however, differences in distribution between ^{238}Pu and ^{239}Pu , as mentioned earlier.

Since there were no long-term low-level experiments completed at the time with ^{238}Pu , Bair (1967) engaged in calculations based on the relative radiation dose around a $0.25\text{-}\mu$ particle of each isotope. Since the much larger dose from

^{238}Pu would be much more likely to be a sterilizing dose, he predicted that ^{239}Pu would be more carcinogenic than ^{238}Pu as long as the dose was large enough to be significant.

A special side study on particle-size effects was possible with the microspheres. Many of them were well above the theoretical cutoff point for "respirable size," viz., $10\ \mu$ to $20\ \mu$. An experimental double check was instituted since the literature seemed to be more theory than practice on the point, or so the investigators felt. They found that $15\text{-}\mu$ particles or larger did indeed never get below the nasopharynx. They were deposited there but rapidly moved to feces. Since then, quite large particles, up to $300\ \mu$, have been placed in animals' lungs by intratracheal instillation. They have remained in situ for many years with relatively little evidence of pathological effects except locally.

In summary, it was clear from the work cited (and it has continued) that there are real differences between the two major isotopes of plutonium (-238 and -239). The ^{238}Pu isotope is more mobile. There is relatively less retained in lung, even with nominally the same chemical forms, and more transferred to bone. These differences and the others make for a potentially different long-term risk from comparable initial activity levels (Bair, Park, and Clarke 1966).

e. Cellular Interactions with Plutonium Particles

This work conducted primarily by C. L. Sanders,^(a) is part of a continuum that it will be more convenient to discuss as a unit in a following section (4 i). Be reminded, however, that a lively program involving the basic interaction between plutonium and biological host cells, particularly macrophages, was under way from the early years of the inhalation program.

f. Nonplutonium Studies

Pulmonary radiotoxicology at Hanford during the decade of the 1960s was, of course, not exclusively devoted to plutonium. There was much carry over from the decade of the 1950s. In chapter 3, we reviewed the quite considerable program in the 1960s and 1970s with radon and daughters and the uranium miner problems. This included some work with thorium (Stuart and Beasley 1967). As part of the therapy program, aerosols of ^{106}Ra , ^{144}Ce , and ^{90}Sr were compared to ^{239}Pu . Americium-241 was studied in part because of its development from plutonium, in part in a separate inhalation experiment aimed at bioassay (Henle and Branson 1969). In the early 1970s, inhalation work with ^{145}Sm and ^{147}Pm and some of the higher transuranics began. We will look at these as part of the next phase.^(b)

4. New Buildings, More Plutonium, More Diversity: The 1970s

Toward the end of the decade of the 1960s, plans were approved to construct a major new facility for the Biology Department in the 300 Area. This was hard by

(a) Charles Sanders is the fourth University of Rochester Ph.D. to become involved directly with the inhalation program at Battelle-Northwest (BNW). Fred Cross, whom we met in chapter 3, also came from Rochester but worked in another division at BNW until his association with the uranium miner work drew him into the inhalation toxicology fold.

(b) Remember, of course, that noninhalation work with many radionuclides was going on in parallel during these years of concentration in the inhalation program on plutonium.

the outskirts of Richland on a beautiful site overlooking the Columbia River. In 1970, the process of moving most of the operation from the outlying 100-F site was completed. The new Life Sciences Laboratory was dedicated in 1971 with historically significant remarks by John R. Totter, director of the AEC's Division of Biology and Medicine; by H. M. Parker, former director of the Hanford Laboratories; and by H. A. Kornberg, who managed the Biology Department for the twenty years from 1948 to 1968 and later was Associate Manager of the Environmental and Life Sciences Division. These are reproduced in the annual report for 1971, published in September 1972 (PNL 1972).

The emphasis on pulmonary radiotoxicology went undiminished in this change. In fact, so many new inhalation experiments were planned that, despite the new space, part of the work (e.g., inhaled uranium mine air contaminants) had to remain in the 100-F Area.^(a) A Life Sciences Laboratory II, built by Battelle, was completed about five years later. These two buildings now contain all active work in pulmonary radiotoxicology.

a. A Second Long-Term Study with Plutonium in Dogs

(Park, Dagle, and numerous collaborators)

The work in the earlier long-term dog study and concomitant work with rodents made it clear that a new experiment would be needed at still lower levels of plutonium.^(b) The extraordinary efficiency of plutonium in causing lung damage of all kinds seen in the decade of the 1960s required this. In addition, life-span studies with ^{238}Pu and plutonium nitrate were indicated by the previous work with dogs (relatively short-term) and rodents.

Therefore, an experiment with over 350 beagles was gradually developed with inhalation exposures to $^{239}\text{PuO}_2$, $^{238}\text{PuO}_2$, and $^{239}\text{Pu}(\text{NO}_3)_4$. The principal investigator for the PuO_2 work was J. F. Park, for the plutonium nitrate work, G. E. Dagle.^(c) Exposures began in 1971 and continued through 1977. Total alveolar deposition and microcuries per gram lung were as follows:

	Initial Alveolar Deposition			Dosage Groups
	Number of Dogs ^(d)	nCi	nCi/g lung	
$^{239}\text{PuO}_2$	130	3.5 - 5800	0.029 - 50	6
$^{238}\text{PuO}_2$	133	2.3 - 5200	0.016 - 43	6
$^{239}\text{Pu}(\text{NO}_3)_4$	105	2 - 5445	0.02 - 47	6

Sacrifices for distribution measurements and pathology reduced the life-span study groups to 108, 113, and 87, respectively. Additional animals were exposed as necessary for periodic sacrifice or tissue distribution work.

The progress of this experiment was summarized regularly by narratives in the annual reports, at several symposia, and by detailed tables at the end of each

(a) Some long-term animal farm operations remained at the 100-F site also.

(b) Remember that new lower levels had to be added in the Utah intravenous experiment (chapter 8).

(c) By this time, Bill Bair had become manager of the Biology Department. He, of course, maintained constant interest in the inhalation program but authored fewer of their progress reports. This second long-term study had the benefit of strong support from Chester Richmond, who was at that time at AEC Headquarters.

(d) Without controls.

annual report, much as was done for the Utah experiments.^(a) In addition to the usual hematologic and pathologic observations, many functional observations were made.

Recent summaries of significant lesions seen in the dogs appear in the annual report for 1981. We will depart from our nominal cutoff time to place as complete information as possible in these pages.

Table 9.8A and B show such a summary of the low-level $^{239}\text{PuO}_2$ and $^{238}\text{PuO}_2$ studies in dogs after 10 and 7.5 yr, respectively.

(a) And, as we will see, for the Lovelace work.

The work with $^{239}\text{Pu}(\text{NO}_3)_4$ is not far enough along to permit a similar tabulation, but Dagle et al. (1982) have presented a summary of both tissue distribution and cause of death in animals up to fifty-nine months after exposure.

The tissue distribution figures are as expected from earlier work with characteristically greater mobility of ^{238}Pu and of the nitrate. *The earliest effect observed with all three compounds was chronic lymphopenia.* This occurred after ≥ 80 nCi of ^{238}Pu or ^{239}Pu in the lung and at higher dosage levels (to date) with the nitrate.

The most striking contrast is the total absence of bone tumors after inhalation of $^{239}\text{PuO}_2$. Lung tumors were numerous, but evidently transport to the skeleton is too low to induce bone tumors in the period under study. With $^{238}\text{PuO}_2$ and $^{239}\text{Pu}(\text{NO}_3)_4$, both bone and lung tumors occurred, some in the same animal.

Obviously, the work is not complete, and the contrast between isotopes and compounds may not be absolute. However, in terms of relative risk, it seems likely that lung will remain at greater risk from $^{239}\text{PuO}_2$. No lung tumors have occurred yet below $77 (\pm 11)$ nCi in lung or $0.56 (\pm 0.07)$ nCi/g initial alveolar deposition of $^{239}\text{PuO}_2$. The final lung burdens are, of course, much lower. There is too much individual variation at the present stage to hazard estimating a mean of the final burdens.

Similar figures for $^{238}\text{PuO}_2$ indicate no lung or bone tumors below $1,300 (\pm 270)$ nCi in alveolar lung or $10 (\pm 1.9)$ nCi/g lung. It is doubtful if this means a lesser effectiveness for ^{238}Pu since the time period is shorter. We must wait out the balance of this experiment to determine minimal effective doses in the dog, if there are any.

The effects of $^{239}\text{Pu}(\text{NO}_3)_4$ are more like those of $^{238}\text{PuO}_2$ in that both lung and bone tumors have already appeared. There were differences in microdistribution in liver between the nitrate and the oxide as determined by autoradiography.

Some cooperative work on bone changes was arranged with the University of Utah to compare the inhalation and intravenous routes of administration.

b. Continued Long-Term Studies with Rodents (Sanders and collaborators)

In addition to the ever-present long-term experiment with dogs, several relatively long-term investigations were conducted with rodents, primarily rats and later hamsters (Sanders and Dagle, 1974).

In a carefully worked-out set of long-term experiments in rats, Sanders (1975a,b) showed that the incidence of lung tumors may be increased following the initial alveolar deposition of as little as 0.15 nCi of $^{239}\text{PuO}_2$. A similar experiment with $^{238}\text{PuO}_2$ showed increased incidence of lung tumors following only 0.07 nCi. Squamous carcinoma predominated at higher deposition levels, adenocarcinoma at lower levels for both isotopes of plutonium. No mention is made of skeletal tumors in these rat experiments.

In work done in 1978, Mahaffey and Sanders (1979) reviewed all of the data on rats (over five thousand animals) for transuranics to extract some risk-estimate figures that could be extrapolated to man. The risk of lung tumors from 1.5 alpha rad per year (the then-permitted dose for occupational exposure) ranged from as high as 1 in 9 to as low as 1 in 120, depending on assumptions. All of these seem unacceptably high.

Multiple exposures to inhaled $^{239}\text{PuO}_2$ were begun by these same investigators in 1978, and studies of the metabolism and late effects of $^{239}\text{PuO}_2$ were initiated in the same year.

The metabolism and late effects of $^{239}\text{PuO}_2$ were compared directly in rats and dogs (Mahaffey et al. 1980). In relation to expected life-span, lung tumors appeared proportionately earlier in dogs than in rats. In this experiment with a direct comparison of a single inhalation exposure to the same aerosol, it also appeared that the dog translocated considerably more ^{239}Pu to thoracic lymph nodes, liver, and skeleton than did the rat at all periods from 15% to 65% of the maximum life expectancy. In fact, liver is *higher* than skeleton in terms of percentage of initial lung burden at all periods in the dog, whereas the two organs are comparable in rats, except for the earliest period (15% to 25% of the maximum life expectancy). This contrasts with some of the MED work.

Sanders has reported on a very low-level life-span experiment in rats (Sanders, Mahaffey, and McDonald 1982). Life-span radiation doses are calculated at from 2 to 100 rad. An interesting twist in this recent work was the addition of ^{169}Yb as a gamma tag for plutonium, an idea generated at the Inhalation Toxicology Research Institute at Lovelace. Despite some dissociation of the ^{169}Yb from ^{239}Pu , reproducible whole-body counts could be obtained at the low levels involved.

The hamsters (Syrian Golden hamsters) were introduced into the plutonium experiments for several reasons: (1) an additional species is always useful; (2) the hamster lung had shown signs of resistance to cancer induction in experiments with radon and radon daughters (chapter 3); and (3) the hamster is less prone to upper respiratory illness, which has always been a problem in rat and mouse colonies. Sanders (1975a,b) used optimal carcinogenic doses for the rat of both $^{239}\text{PuO}_2$ and $^{238}\text{PuO}_2$. There was no question that the pathologic response was different in the hamster. The primary cause of death at the higher doses was radiation pneumonitis, not different from other species—but at lower doses; amyloidosis and chronic nephritis were much more common. While there was considerable pulmonary adenomatous metaplasia in the hamster lung in the highest exposure groups, there was only one primary lung tumor in 172 necropsied hamsters. *The lung cancer resistance seen with other radionuclides thus seemed to extend to plutonium.* The distribution to tissues of the inhaled plutonium was quite similar in rat and hamster. Therefore, the difference in tumor incidence cannot be explained by a difference in tissue content. A full explanation might offer some clues to the mechanisms of carcinogenesis.

c. Exposure of Swine to Plutonium Aerosols

In 1975, work was carried out on techniques for exposure of miniature swine to inhaled aerosols (Karagianes et al. 1976). In view of the central role this animal has played in other Hanford programs, this extension is not surprising. A single exposure to $^{239}\text{PuO}_2$ is reported with results “encouragingly similar” to the distribution pattern established for dogs and rodents. However, the work seems not to have gone much beyond establishing the feasibility of using miniature swine for inhalation work.

d. Plutonium and Cigarette Smoke

We reviewed in chapter 3 some of the Hanford work in which beagles were taught to smoke cigarettes through a mask arrangement. This was especially pertinent because the miners tended to be heavy smokers.^(a) A picture of the special mask assembly is shown in figure 9.21.

(a) This was not universally true, as also discussed in chapter 3.

FIGURE 9.21. Mask assembly for the smoking beagles. (Photo courtesy of Pacific Northwest Laboratory.)

The chance of simultaneous exposure to plutonium and to cigarette smoke in ordinary occupational exposure is slight because of the rigid rules against smoking in the work areas and the frequent wearing of face masks. Nevertheless, the possibility that cigarette smoking might alter the lung transport processes, as well as the sensitivity of the critical cells for cancer development, led the Battelle investigators to check out the basic phenomena in both rats and dogs. It is applicable to both occupational and potential population exposures.

It appears that this additional work with cigarette smoke had to await the move to new facilities and lagged considerably behind the companion work with radon, uranium ore dust, and diesel smoke. It was not begun until 1978. In 1980, work on the influence of smoking on plutonium clearance and effects was described in detail. It started with rats (Filipy et al. 1980). For this work, the cigarette smoke was produced by a special device (Walton Smoke Exposure Machine®) and given in ratios of 1/10 of smoke to air. At the end of a seven-month period of exposure to cigarette smoke, one group of thirty-five rats received a single inhalation exposure to $^{239}\text{PuO}_2$ to produce an initial lung burden of 50 nCi. There were, of course, groups receiving only the plutonium and a sham smoke \pm plutonium. The smoke-exposed groups cleared plutonium from the lungs significantly more slowly than the others. The delay in lung clearance would presage a greater risk of lung cancer, unless other factors intervene.^(a)

® Process and Instrumentation Corporation, Brooklyn, New York.

(a) The reported delay in clearance is not consonant with experiments in man, some of which have indicated more rapid clearance in smokers, also increased mucus secretion, both of which might provide protection rather than exacerbation.

A similar experiment with trained beagles was reported (Filipy et al. 1980). The inhibitory effect on pulmonary clearance of $^{239}\text{PuO}_2$ seen in rats was confirmed in the dog. The initial lung burdens were $0.3\ \mu\text{Ci}$ to $1.4\ \mu\text{Ci}$, and a difference in clearance rate between young and old dogs was noted.

Incidental to the development of the work in dogs was the fabrication of a new exposure valve assembly for switching to the lighted cigarette (research cigarettes from the University of Kentucky). In the old system used for the uranium mining work, a solenoid valve was used which produced a loud click on the switch to cigarette smoke. Evidently some of the dogs did *not* enjoy smoking^(a) and learned to use the audible click as a cue to draw only a quick, shallow breath. This quickly switched the valve back to fresh air. By measuring blood levels of carbon monoxide hemoglobin, it was clear that there was considerable variability among dogs in the amount of smoke inhaled. With the newer system, a motorized pump with no cues to help the dogs beat the system, more uniform exposure to the smoke was found.

e. Plutonium-Sodium Aerosols

Toward the end of the decade of the 1970s, the Battelle group attacked questions surrounding the planned liquid metal fast breeder reactor (LMFBR), which uses liquid sodium as a coolant. They engaged in study of both sodium aerosols and of potential mixtures of LMFBR fuel with sodium aerosols. They were not alone in this new work and concentrated on behavior after inhalation.

First, the technical problems were attacked of producing an aerosol that might simulate one produced in possible core melt-down and release of an Na-(PuU)O_2 aerosol into the environment. This was accomplished by laser vaporization of reactor fuel (Briant and Allen 1981).

Biological behavior was looked at in both dogs (Hackett et al. 1981a) and rats (Hackett et al. 1981b). Initial pulmonary deposition was greater for fuel aerosols, but the rate of pulmonary clearance of sodium-fuel aerosols was higher, and larger fractions appeared in blood, liver, and skeleton. Chemical work indicated a solubilization reaction *in vitro* in the presence of sodium. Much less of the sodium-fuel aerosol went to thoracic lymph nodes than from aerosols of fuel without sodium. Results with dog and rat were comparable.

This work is being continued, but we are already well beyond our nominal cutoff date and must desist from further discussion. In view of the uncertain future of the LMFBR, the subject of sodium-fuel aerosols may become of only academic interest. Even so, the fact that these changes in chemical constitution can cause differences in pharmacokinetics has a significant influence on health protection activities for this and other new technologies.

f. Transplutronics

While the behavior of elements such as americium was not neglected in the earlier years of research at Hanford, a more sustained effort concerning inhaled transplutronics occurred in the decade of the 1970s.

In 1973, the two plutoniums (-239 and -238) were compared to $^{244}\text{CmOx}$ in rats. Fresh $^{244}\text{CmOx}$ (calcined at 750°C) was highly soluble in lung with correspondingly higher depositions in liver and bone than plutonium. Survival time

(a) Evidently I was misled by personal observation of the blissful expression on the dogs' faces and comments from the operators into thinking all the beagles enjoyed their smokes (see chapter 3).

of the animals was shortest for curium. In fact, it was so short that there was not time for development of pulmonary metaplasia or neoplasia (Sanders, Craig, and Smith 1974; Sanders 1974).

In the same year, work on inhaled and intravenously instilled ^{253}Es was described in rats (Ballou 1974; Ballou, Busch, and Dagle 1974). Three forms were used, and intratracheal instillation was resorted to for part of the work because of the limited quantity of einsteinium available. The two routes were comparable except for the hydroxide. Radiation pneumonitis predominated at the highest dose, osteosarcomas at the intermediate dosages, and soft tissue tumors, including lung tumors, at the lowest dose. More pathologic observations came along in the next year. These indicated some bone tumors and fewer lung tumors for ^{253}Es compared to ^{239}Pu . The researchers speculated that einsteinium was even more a surface seeker in bone than plutonium.

By 1978 (Ballou et al. 1979), there had been time to follow late effects after inhalation. The high incidence of bone tumors and relatively fewer number of lung tumors seen after intratracheal instillation were not seen in the work with inhaled $^{253}\text{Es}(\text{NO}_3)_3$. This was puzzling because the calculated radiation dose to the lungs was higher after instillation, yet the incidence of lung tumors was higher after inhalation. The authors argue that the inhaled einsteinium is more uniformly distributed after inhalation and irradiates more sensitive tissue. Furthermore, those rats receiving high skeletal doses after inhalation also had severe lung damage, which resulted in early death due to radiation pneumonitis.

Exposures were made to study the carcinogenic effect of high-fired $^{241}\text{AmO}_2$ in rats. Lung clearance was rapid, as it was with cerium. At most, only lung and liver tumors have been seen. Despite its mobility, $^{241}\text{AmO}_2$, in this study at least, seems to be ineffective as a producer of bone tumors. By contrast, $^{241}\text{Am}(\text{NO}_3)_3$ is very rapidly removed from the lungs and is conspicuously effective in producing bone tumors.^(a) Furthermore, the calculated radiation doses to bone were only one-half those to the lung. This work seemed to need extension and confirmation. It got it in the next year, and it appeared that the special effectiveness was in the animals receiving 100 to 1,000 rad. In general, ^{241}Am seemed no more effective than plutonium or einsteinium in producing lung and bone tumors after inhalation.

Very recently, inhalation work with americium has been extended to the dog. This work includes a number of serum chemistry parameters. It should provide a useful contrast to the americium work at Utah using intravenous injection.

g. Thorium-Cycle Nuclides

In the chapter on uranium, and again in chapter 8, we bemoaned the lack of interest in radionuclides specific to a potential thorium fuel cycle. Following an essentially silent period after the war, except for tracer applications of the shorter-lived uranium isotopes, several laboratories have begun serious efforts to fill in the gaps by studying those radioisotopes more or less unique to the thorium fuel cycle. Inhalation work with some of these has been taken up in a modest way by Battelle at PNL. It can be seen in the 1979 annual report in work by Ballou and colleagues (Ballou, Gies, and Case 1980; Ballou, Gies, and Beasley 1980) on $^{232}\text{UO}_2(\text{NO}_3)_2$ and $^{233}\text{UO}_2(\text{NO}_3)_2$ and comparative toxicology of inhaled

(a) Usually differences in the type of compound of a radioisotope do not produce such a striking contrast in effectiveness. This is more like chemical than radiation toxicology.

actinide nitrates. The two uranium isotopes, despite some possible differences in pharmacokinetics (which, if real, may be related to factors other than isotope differences, e.g., the development of daughter products of ^{232}U), appear to have roughly comparable toxicity after inhalation. Both go primarily to skeleton.

The authors comment in the second paper that no "unusual toxicity" was found to be associated with inhalation of high-specific-activity isotopes of uranium in comparison to other actinide nitrates. This is not surprising since it is clear that uranium, while it moves to bone quite readily, is a volume rather than a surface seeker. Thus, any possible increase in bone tumorigenesis by virtue of greater translocation to bone may be modified by the site of deposition. A careful analysis is made of the possible reasons for the differences.

Later work tried intratracheal instillation of a solution of ^{232}U in equilibrium with its daughter products (^{228}Th , ^{224}Ra , ^{212}Bi , and ^{208}Tl). To do this, simultaneous measurements had to be made on several tissues by having three germanium detectors operating together. As seen in similar work using other routes of entry, the tissue distributions were decidedly not those of an equilibrium mixture. The details of nonequilibrium were different after inhalation from those after other routes of administration. This was reported by Ballou and his colleagues in 1981.

Also, ^{231}Pa , a major long-lived waste product of the thorium cycle, was introduced. This work is continuing.

h. Aerosol Science

Earlier in this chapter we reviewed briefly the development of aerosol science in the various laboratories. We noted that Hanford did not in general separate out aerosol work as a distinct entity. In this final decade of our consideration, both specific papers and groupings of summaries of aerosol work at this laboratory have appeared. These have considered the usual problems of relationship between size distribution, concentrations, and behavior; deposition, particularly alveolar deposition, as a function of both respiratory and aerosol parameters (see papers by D. K. Craig et al. in reports from 1971 through 1974) and some fairly elaborate methodology for determining respiratory parameters and their importance to deposition in various portions of the respiratory tract. Craig et al. (1972) obtained complete respiration data on ninety-eight dogs during the period of training and used these to compare with similar parameters obtained during exposure. Thus, predictions can be made for relatively short exposure periods. This work correlates closely with a remote control and measuring system developed at Rochester, which we will consider presently.

A final^(a) note on contributions of the aerosol group to the pulmonary radiotoxicology unit is seen in figure 9.22A and B. This represents what must be the ultimate in nose-only exposure chambers built to prevent rebreathing (Cannon, Blanton, and McDonald 1983, Cannon et al. 1982).

In figure 9.22A, the conventional method is diagrammed. In figure 9.22B, we see how separation of incoming and outgoing airstreams can be accomplished. This makes the rat nose-only exposure system more comparable to the mask and valve array used for the dogs.

(a) Except for the fact that they were drafted into characterization of Mount St. Helens volcanic ash. It was nearly inert compared to quartz particles.

i. Basic Overtones

As we have seen, most laboratories with large long-term experiments under way did much work simultaneously on mechanisms. In the inhalation program at Hanford, a steady effort was maintained in several quarters. Chief among these was work on cellular interactions of plutonium carried out by Charles L. Sanders and collaborators. We will consider this work briefly in this final section. It extends over a considerable period.

Much interest attaches to the interactions between plutonium and the cells and tissues it comes in contact with. Biochemical phenomena have been observed in some depth (Taylor 1973a), and details of interactions with the cells of bone and bone marrow have been examined all over the world. It appears, however, that much less time has been devoted to these basic phenomena for inhaled radionuclides. For many years, only two names came readily to mind for work concerning the response of cells to an inhaled plutonium dioxide particle, Louis J. Casarett at the University of Rochester and Charles Sanders (a Rochester graduate) at Battelle. On the theory that the macrophages would be the cells most involved in such interactions, Sanders began with the peritoneal macrophage of the rat (Sanders 1969a). After perfecting techniques, the work was shifted to pulmonary macrophages (Sanders 1969b) and the gradual working out of the sequence of events. The plutonium was deposited in the peritoneal cavity or lung, which was then washed with sterile saline,^(a) and, thus, the plutonium was deposited in the peritoneal macrophage (Sanders 1969a). The time of application of the wash was varied in different experiments to provide both composite and serial pictures. The cells were washed and separated from other materials and prepared for light or electron microscopy, autoradiography, counting by DNA assay, and other treatments.

There was no doubt that plutonium particles were rapidly phagocytized by both peritoneal and alveolar phagocytes. By two hours after emplacement, over 90% of the plutonium particles had been phagocytized in the peritoneal cavity. The alveolar macrophages worked a bit more slowly, not reaching the approximately 90% level until after a day or more of contact.

The relation of quantity of plutonium in the lung and the phagocytic index (percentage of macrophages that had engulfed particles) is shown in figure 9.23.

FIGURE 9.23. Correlation between phagocytic index and log of amount of plutonium present in rat lung. (Samples obtained from 1 hour to 25 days after exposure. Correlation coefficient is 0.91. Outer solid lines represent 95% confidence intervals around regression line and outer dashed lines represent 95% confidence intervals for individual samples.) (Redrawn from Sanders via Bair 1970.)

(a) The washing process in lung gave many leads toward possible therapy, which we will take up in chapter 19.

Using a rather elegant technique of electron microscopic autoradiography, to which Sanders contributed importantly, as well as light microscopy combined with autoradiography, it was possible to observe details of the intracellular localization of plutonium within pulmonary macrophages. It is concentrated in the phagosomes of these cells. Frequently, quite striking amounts of plutonium would be accumulated within macrophages, e.g., a 500-fold concentration by peritoneal macrophages compared to the initial concentration in the peritoneal cavity. Indeed, accumulations were sometimes enough to interfere with preparation of thin sections by refusing to be cut through.

Such high concentrations of alpha radiation exacted a toll of the engulfing cells. Various stages of cytotoxic changes were seen developing, going into eventual cell disintegration. However, other macrophages came along to engulf both the plutonium and the cell debris, and the process was thus continued. In fact, it is not possible to tell in many cases whether the concentration seen in a given cell represents its own work or the engulfment of material already concentrated by previous phagocytic processes. However, it appeared that a single macrophage could retain plutonium particles for many months, thus accumulating a very large radiation dose.^(a)

The amount of plutonium in the alveoli influenced the amount found in macrophages, as shown in table 9.9.

TABLE 9.9. Influence of the Amount of Alveolar $^{239}\text{PuO}_2$ on the Concentration of PuO_2 in Alveolar Macrophages. Alveolar macrophages were removed from rat lung at 1-15 days after inhalation of PuO_2 by one 12 ml saline washing. Autoradiograms of macrophages on cytosmeareds were exposed for 14 days. Only alpha tracks passing outside the cell were counted.

\propto Tracks per Macrophage	Mean distribution in each class (%)		
	Mean Amount of ^{239}Pu in Lung (μCi)		
	0.03	0.4	1.7
2-5	51.3	18.5	8.2
6-30	39.8	36.1	25.4
>30	8.9	45.4	66.2

Source: Reset from Sanders 1972. Reprinted with permission of Pergamon Press, Ltd., Elmsford, New York, copyright 1972.

The retention half-time for PuO_2 in lung macrophages also varied with plutonium concentration (Sanders 1972). For example, with a mean lung burden of $1.7 \mu\text{Ci/g}$ lung, the retention time was about three days; with $0.06 \mu\text{Ci/g}$ mean lung burden, the retention time was over thirty days. This may reflect the killing of cells by the higher radiation doses. Sanders has also worked out intracellular particle size distributions and, thus, distribution of cellular dose, which is illustrated in table 9.10 taken from Sanders's work.

Obviously, the macrophages were transported by the lymph stream or transplanted themselves to areas such as pulmonary lymph nodes. It appears that

(a) Thus placing them among the most radioresistant of cells.

TABLE 9.10. Distribution of ^{239}Pu Activity Amongst Particles of Various Sizes Within Alveolar Macrophages Obtained by Saline Washings at 1-34 Days After Inhalation of $^{239}\text{PuO}_2$ by Rats. The amount of plutonium in 800 macrophages was autoradiographically determined in 8 exposed rats.

Fraction of $^{239}\text{PuO}_2$ -Laden Macrophages (%)	Equivalent* Particle Diameter (μm)	Amount of ^{239}Pu in Particle (μCi)	Fraction of Macrophage Plutonium in Each Size Class (%)	Radiation Dose† to Macrophage (rad/hr)
50	0.12	5.8×10^{-10}	2.5	0.5
24	0.16	1.4×10^{-9}	2.9	1.2
10	0.18	2.0×10^{-9}	1.7	1.8
4	0.20	2.9×10^{-9}	1.0	2.4
4	0.22	3.6×10^{-9}	1.2	3.2

most of the plutonium (and probably most of the majority of other heavy metals) concentrated in lymph nodes arrived in a macrophage. The basis for this conclusion is the fact that particles that were not phagocytized were rapidly cleared from the lung, and lung clearance after the first few days (in the rat at least) is almost all by or in pulmonary macrophages. *Thus, kinetics of movement of plutonium depends on macrophage kinetics.*

Sanders believes his findings explain the long retention time of plutonium in lung (Sanders 1972). The steps are immobilization of plutonium-laden macrophages in the alveoli, rapid engulfment by the alveolar epithelium, transport to the lymphatics, and sequestration in fibrotic zones of pulmonary tissue.

A final step (for purposes of this review) is the tracing of plutonium dioxide in the lung from macrophage to carcinoma. In an intriguing but somewhat complex discussion at a 1977 Hanford biology symposium^(a), Sanders et al. (1977) traced quantitatively the movement of plutonium in rat lung and the accompanying radiation dose. Despite the movement of macrophages, 80% of the energy absorbed is calculated to be delivered to alveolar septa. Of this 80%, only 10% each is absorbed by alveolar epithelium, macrophages, and endothelium, while 70% is absorbed by other elements present. Alveolar epithelium is an important target tissue, but neither it nor bronchiolar epithelium receives more than a small fraction of the total dose. When it is considered that a total dose of 78 rad delivered to *whole lung* of the rat over a period of about six hundred days produces a significant incidence of pulmonary adenocarcinoma,

(a) A glance at the table of contents of this symposium is enough to convince anyone that basic processes in the lung were not being neglected.

and the total energy calculated to be delivered to Type II alveolar epithelium or bronchial epithelium may be a small percentage of this, it is natural to ask if these very small amounts of energy can really cause the changes needed to produce a neoplasm. Is it due to the concentrated dose (which is, of course, much higher than the average dose) from the macrophages? Or is it due to a high early dose rate? To some other reason? Is there some mistake? The histological signs were largely negative at such doses. Also, why do adenocarcinomas predominate at low radiation doses, while squamous cell carcinomas are more characteristic of higher doses? The work at Hanford has made a start on these questions. We will have occasion to return to some of these problems when we look at the "hot particle" problem in lung.

A natural extension of the above work was to study the interaction with radioactive materials of phagocytic cells in in-vitro cultures, which Schneider and Robinson (1978) did in 1977. They could conclude, using two forms of plutonium and $^{241}\text{AmO}_2$, that the cellular effects seen are truly radiation, not chemical toxicity effects.

This work with macrophages is, of course, only an example of the basic overtones that accompanied the Battelle program. Since these were excellent scientists, they always looked for clues as to mechanisms. The histopathology reports are especially indicative of such interests and the generation of new information pertinent to mechanisms. Other areas were biochemical changes in lung, pharmacokinetic explanations for the differences in lung tumor response among species, pulmonary function evaluations, and others.

There is not room in these pages to follow these ideas in depth for each installation since both the basic problems and the attacks were similar in many laboratories. The easiest way to follow these is through the review papers, which sum up ideas developed over considerable periods. Many of those from Hanford have already been cited. Others that concentrate on pulmonary radiotoxicology are Bair et al. (1973); Dagle, Lund, and Park (1976); and Park et al. (1970). There was also work on biochemical mechanisms in the lung carried out by Tombropoulos et al. (1977), among others.

Comment: During the last decade that we have been reviewing, the Battelle people (along with others) expanded and diversified into other energy technologies, first under ERDA and then under the DOE. Much of the new work involved inhalation experiments. The superposition of these new enterprises put a real strain on both facilities and personnel; for it was unthinkable to give up the investment in the long-term studies and the unique expertise of the laboratory. Fortunately, the problems are not really very different, only the techniques. It is to the group's credit that they accommodated well and seemed to be able to attack the new without losing the essence of the old.

B. Lovelace Foundation—Inhalation Toxicology Research Institute^(a)

The Lovelace Foundation project was the last of the "king-sized" postwar experiments in internal emitter toxicology (chapter 8). It was the only one devoted exclusively to pulmonary radiotoxicology. It began as the "Fission Product Inhalation Laboratory" of the Lovelace Foundation and kept this name for many

(a) I have leaned heavily in preparing this narrative on an informal summary kindly provided me by the Institute's Director, Dr. Roger McClellan (1981).

years. As its mission and that of the host institution expanded, it was renamed "The Inhalation Toxicology Research Institute" (ITRI), the name it still bears.

1. Concept and Organization: Initial Activities

During the 1950s, the mounting concern for the effects of the radionuclides in fallout from the weapons testing program stimulated many new experimental efforts.^(a) The demands of the Aircraft Nuclear Propulsion (ANP) project, along with reactor safety considerations, added to the perceived needs. Despite the active programs at Utah and Davis, which concerned intravenous and oral routes of administration, and the inhalation work at Hanford, a major program devoted to the *inhalation of fission products* was considered essential.

As we saw in chapter 8, the capabilities of existing laboratories were always considered first before initiating a new project. The prime candidate was Rochester. However, the size of the program planned made the Rochester location on a relatively compact campus in the northeastern climate undesirable. Furthermore, Rochester was already involved in the long-term uranium experiment and in other research in pulmonary radiotoxicology and aerosol science. Full commitments to other programs or problems of space for expansion dissuaded the planners from other locations also. These included Hanford, Davis, and the Argonne National Laboratory.

There then occurred one of those happy coincidences that influence the development of science as well as other facets of human activity. The Lovelace Foundation for Medical Education and Research, which started as a largely clinically oriented group in Albuquerque, New Mexico, had developed during the early and mid-1950s strong activities in aviation medicine and pulmonary physiology. As a part of this, they had engaged in research on the biological effects of blast, initially for AEC, later for the Department of Defense (DoD). The facility for this work was located on an outlying area of Sandia Base, a few miles from the Lovelace Clinic, which was itself on the edge of the desert base. The blast biology work was winding down. W. Randolph Lovelace, Jr., son of the founder of the clinic, evinced interest in some new work. Dr. H. D. Bruner, who had major responsibilities at AEC Headquarters for the administration of the pulmonary radiotoxicology work (Bruner 1979), learned of the interests at Lovelace. Headquarters staff already knew the clinic's other work in respiratory physiology. Thus, in June 1959 the Division of Biology and Medicine of AEC contacted Dr. Clayton S. (Sam) White, who was then Director of Research for the Lovelace Foundation and who had managed the blast biology program, relative to taking on a project on the effects of inhaled fission product radionuclides. They were interested, and a plan was submitted in January 1960. By June 1960, a contract was awarded. On the Lovelace side were Dr. White and W. R. Lovelace, Jr. (Randy). On the AEC side were Dr. Bruner and, backing him both scientifically and administratively, Dr. C. W. Shilling, deputy director of the Division of Biology and Medicine.^(b) The nearness to Sandia Base and Kirtland Air Force Base was a plus because of the presence there of many radiation physicists and chemists.

(a) We will review the broad picture of such research in chapter 13.

(b) It was my privilege to visit Randy Lovelace and Sam White in Albuquerque in company with Dr. Shilling and to be present at part of the "keel laying" activities for this important new enterprise. Dr. Shilling is a retired Navy Captain, so the keel laying analogy comes naturally.

There were no formal "Founding Fathers" for this project. There was considerable information and planning exchange with other laboratories doing inhalation work. This was accomplished partly through the AEC Headquarters staff, particularly Dr. William Lotz, who had assumed some of the administrative work for the internal emitter research with H. D. Bruner. A group called the "Inhalation Toxicology Working Group" met rather frequently at the cognizant laboratories. There were representatives from each of the major inhalation programs in this group. There was also a small advisory committee to assist Drs. Bruner and Lotz. Some meetings of the latter group placed special emphasis on the developing plans of the Lovelace experiments and were held at Albuquerque.

Randy Lovelace placed Sam White in charge of developing facilities and assembling staff. The remainder of 1960 was spent on these plans, plus the preliminary design of experiments.

In January 1961, T. T. (Tom) Mercer, whom we met in the section on aerosol science, arrived at Lovelace with a Ph.D. from Rochester and experience in England, at the Naval Radiological Defense Laboratory, and the University of Washington. He set to work immediately on the research required to produce and characterize the radioactive aerosols needed. The aerosol physics section, which he started, has been a powerful and productive one ever since.

In February 1961, Robert G. (Bob) Thomas arrived from Rochester to establish a radiobiology section. He laid plans fairly soon to have the respiratory parameters measured and recorded on *each and every animal exposed*, small or large.

The reason for this decision deserves attention. Over the years, inhalation exposures had characteristically involved either placing animals in a chamber whose ambient air contained the substance of interest or arranging the "nose-only" procedure, where only the tip of the animal's snout protruded into the aerosol stream. With the former method, there are always questions regarding intake by licking the fur and the uniformity of distribution of the material in the chamber. With the nose-only method, the contamination of fur is eliminated, but it is still necessary to estimate intake by calculation from the exposure concentration. As we have already seen, special equipment has been designed and used at Hanford and Rochester to measure deposition as well as many other respiratory parameters directly. But the Lovelace idea of measuring tidal volume, ventilation rate, etc., for each individual animal was a new and somewhat heroic development. The result, a knowledge of how much each animal took in, was considered worth the effort. A bit further along we will see how it was managed.

By the end of February 1961, White, Mercer, and Thomas submitted plans for a facility and a program. In less than two weeks, the plan had informal approval with instructions to develop initial experiments and to complete the building plans.^(a) By June, a contract was let for design and construction of a facility on the southern part of Sandia Base to accommodate work that had to be somewhat isolated.

A unique facility was planned which, among other things, utilized the abundant evaporative potential of the desert climate to greatly reduce the volume of liquid waste requiring disposal by the use of open holding ponds. Good separation of "hot" and "cold" operations was facilitated by the abundance of land to spread out upon. A purebred beagle dog colony was begun in 1961 using dogs

(a) Such timing is more like the Manhattan District days than current bureaucracy. It attests to the confidence the people and plans commanded at AEC Headquarters.

from some of the other large AEC projects and also commercial breeders and experience gained in the already existing colony at Hanford. The details of development and the care and breeding of this colony have been given by Redman et al. (1970). Redman joined the staff in September 1961.^(a) The interim facilities for the dog colony and for some of the experimental work were ready by late summer 1961.

In June 1961, Ms. Randi Lie (later to be Mrs. Robert Thomas) joined the staff with an M.S. degree from Rochester. In December 1961, Dr. Bruce Boecker with a Ph.D. from Rochester and experience with field release studies of fission products while a graduate student (see chapter 14) joined the group. Experimental work began in the Headquarters facilities of Lovelace Foundation.

Bruce Boecker and Bob Thomas worked in parallel on developing apparatus and protocols for exposure of small rodents (Thomas) and dogs (Boecker), while Mercer worked on the aerosol generation problems as well as basic aerosol science.

Following the plan that each animal should have its respiratory parameters measured during exposure, plethysmographs of varying size and design were created and tested. Some of the early ones for rats, along with old and new exposure chamber designs, were described by Thomas and Lie (1963) in a moderately early "LF" report. This report includes also the full procedural protocol for the small-animal work.

A diagram of this exposure assembly is shown in figure 9.24. Note that a body plethysmograph was attached to each of the several openings in the chamber.

The corresponding development for dogs was described by Boecker, Aguilar, and Mercer (1964) at the Hanford symposium on Inhaled Particles and Gases. Because it was desired to keep animal movements from becoming extreme and thus interfering with the plethysmograph record, the dogs were placed in a sling, which was in turn placed in the chamber-plethysmograph. In order to isolate the system from the room air and prevent changes in room air pressure (e.g., door opening) from causing wide fluctuations in the pneumotachograph base line, a compensatory chamber was arranged atop the exposure chamber-plethysmograph. The pressure changes were, of course, sensed by transducers and recorded.

The reading of separate plethysmograph records for each animal was a most laborious and time-consuming process. It was not long before an automated system was designed and put into operation (Goodrich and Thomas 1963).

While this work was in progress, some of the biomedical personnel in the Foundation in fields like biochemistry, microbiology, and pathology were oriented into the program for studies of radiation effects. Dr. Robert K. Jones, an M.D. pathologist from the University of Cincinnati with Air Force experience, joined the group in August 1964. He joined Dr. James Scott from Rochester and the University of Virginia who came in 1962 as the second full-time pathologist to the program. Others were Dr. T. Chiffelle, pathology; Dr. B. Longwell, biochemistry; and Dr. W. Clapper, microbiology. These portions of the program were accommodated in a major expansion of the Lovelace Headquarters facilities begun in 1962.

(a) Dr. H. C. Redman graduated from the University of California at Davis in Veterinary Medicine. He had experience while a student working at the Nevada Test Site (UCLA Project) and service in the Air Force at the Radiobiology Laboratory at Kirtland Base in Albuquerque.

FIGURE 9.24. Early Lovelace exposure assembly for small animals. (Redrawn from Thomas and Lie 1963.)

It was decided early that the complexities of handling and exposing animals to mixed fission products posed undesirable problems. Therefore, much of the early work utilized ^{137}Cs . Because of pressures from the field problems, some effort went also into the burning of fuel elements, but this never reached the stage of exposing animals at Lovelace.

The earliest "LF" reports and publications related to aerosol science and the development of equipment. A string of reports and publications by T. T. Mercer concerning primarily the cascade impactor resulted from work during this early period. A sampling of these is Mercer, Tillery, and Ballew (1962); Mercer (1963, 1964, 1965). An excellent overview of these and other developments is given by Raabe (1970 and 1972), and we thus can refrain from further detail here.

Later developments in aerosol science were the decision to use stable cesium chloride as a common vector for the "soluble" aerosols and the development of

a standardized "insoluble" carrier, fused montmorillonite clay particles.^(a) The technique for the former was to add the radionuclide of interest to a cesium chloride solution. (Controls of cesium chloride alone were always run.) For the insoluble vector, the radionuclide of interest was attached to montmorillonite clay by ion exchange, an aerosol of labeled clay particles generated and treated at high temperatures to fuse the particles into a relatively insoluble form. Thus, the aerosols used for the main thrust of the Lovelace program were different from those used at Hanford, Rochester, and elsewhere. The theory was that particle size and solubility, being properties of the vector, would be more constant and controllable than they were with aerosols made up idiosyncratically for each radionuclide. The advantages are numerous if dosage pattern is to be controlled reproducibly, and this was the intent of the Lovelace experimenters. There are disadvantages too. Perhaps the primary one is that behavior of the administered radionuclide may be submerged in behavior of the carrier particles. However, experiments at other laboratories were checking on these points. Also, some sort of vector is present for most radioactive aerosols, and there are advantages in having only two vectors, one for soluble aerosols and one for insoluble.^(b)

Only a few results beyond aerosol techniques and laboratory and experimental plans will be considered in reviewing this initial phase of the Lovelace work.

Thomas (1964b)^(c) developed theoretical functions for predicting the concentration of materials in lung and lymph nodes following inhalation and compared them to experimental studies from a number of laboratories, including Lovelace. Lie (1964) published some of the early work in rats with ^{137}Cs inhaled in two forms, chloride and nitrate. Greater amounts were deposited at the larger particle sizes. Retention kinetics seemed not to be influenced by the particle sizes inhaled. This result is somewhat contrary to experience with uranium and in other laboratories with other materials. It may or may not be actually different. The particle-size range was not large, about $0.3\ \mu$ to $1.9\ \mu$ "equivalent diameter" (standard deviation not given), but in the range of the other experiments. It cannot be determined whether this reflects behavior of cesium or the fact that the experimental technique allowed determination of actual deposition in each animal. Also, concentration (i.e., initial deposition) in lung, kidney, and liver was greater at smaller particle sizes, consonant with other work.

2. The Major Programs Begin

Even though the period 1960 to 1964 was far from inactive, the emplacement of large, in contrast to range-finding, experiments had to await the completion of facilities on the Sandia Base safe for handling aerosols with penetrating radiation and the presence of adequate senior and supporting staff.

In October 1963, there was a program review of the Lovelace project in conjunction with a meeting of the AEC Inhalation Toxicity Group. There was general agreement to continue the work with several animal species and to have as balanced a program as possible. Because of the complexities of a dog program, emphasis was placed on getting started with exposure of the beagles.

(a) A hydrous aluminum silicate found at Montmorillon, France. This will be abbreviated to "FAP"—"fused aluminosilicate particles"—in subsequent discussions.

(b) This general plan was later expanded for the long-term experiments (see next section).

(c) This paper was widely circulated, and versions appeared also in proceedings of the IAEA and the Bioassay Group.

The first dog was exposed to a radioactive aerosol in the permanent Lovelace facilities on January 29, 1964. This followed up the work with rats and used a ^{137}Cs chloride aerosol. There thus began a major program that is still in progress. For many years it stuck closely to the original charge, viz., to study the pulmonary radiotoxicology of the biologically important fission products. Despite the work we have already seen from the World-War-II years and individual experiments elsewhere, this was the first major coordinated long-term study of fission products by the inhalation route in a large animal.

In addition to ^{137}Cs , Lovelace added ^{91}Y , ^{144}Ce , and ^{90}Sr , all as chlorides and thus a relatively soluble form. The development of the technique for preparing fused montmorillonite clay as a carrier added the potential dimension of an insoluble form for all of these radioisotopes. Strontium-90 titanate was also used as a relatively insoluble form of this element. The FAP experiments included $^{90,91}\text{Y}$, ^{144}Ce , and ^{90}Sr . The exposures began with young adult beagles, thirteen months of age. Gradually, experiments were added with $^{144}\text{CeO}_2$ using Syrian hamsters of different ages; ^{90}Y FAP, $^{144}\text{CeO}_2$, and ^{141}Ce FAP in mice; and $^{144}\text{CeO}_2$ in rats. We will save discussion of the long-term results for a consolidated look in a later section.

This period was not all uninterrupted progress. In summer 1965, Tom Mercer left Lovelace to go back to Rochester to head up their basic aerosol program. As we saw in the section of this chapter on aerosol science, Bob Thomas filled in the gap in addition to his other work. Otto Raabe arrived near the end of 1966, and George Kanapilly came in 1967. Fortunately, the basic aerosol techniques had been worked out by Mercer with Thomas helping to apply them to the animal chambers. Thus, the hiatus in aerosol science did not delay the exposures. The new arrivals had different basic interests, which we will see presently.

Also in 1965, the AEC Division of Biology and Medicine sponsored another review of the Lovelace activities. At this meeting, Dr. H. D. Bruner's growing concern that not enough attention was being devoted to studies with dogs was aired. The original Lovelace design to have many species and much probing done with short-lived species still made scientific sense, but Headquarters seemed to have difficulty financing broad programs at several places and considered the Lovelace program as a "dog program" like Utah and Davis. After the meeting, the Foundation was directed to shift major emphasis to life-span studies with beagles.

In December 1965, W. R. Lovelace II was killed in a private airplane crash in the Colorado Rockies. Changes in the Foundation's leadership had to follow. Clayton White became president of the Lovelace Foundation and decided he could no longer manage the fission product research program. Through a series of fortunate coincidences, Dr. Roger O. McClellan was finishing up a tour of duty at AEC Headquarters, where he had been on leave from the Hanford Biology Operation. He had experience with radioisotope problems dating to summer work at Hanford in 1957, 1958, and 1959; a degree in veterinary medicine from Washington State University; and subsequent experience with internal emitter research at Hanford and on his assignment to Headquarters. On September 12, 1966, Roger McClellan became director of the Fission Product Inhalation Program at Lovelace. The program has prospered ever since.

One of Dr. McClellan's first actions was to push completion of the exposure of the dogs according to plan. He also began adding some needed professional personnel, e.g., Antone L. Brooks, a recent Cornell graduate in cytogenetics.

The exposures to ^{90}Sr chloride, ^{144}Ce chloride, and ^{91}Y chloride were well under way in late 1977 when the Foundation sponsored a meeting (the first) of its own review panel. The original plan of exposing groups of dogs to both soluble and insoluble forms of many different elements and using at least three exposure levels had begun to look overwhelming, if not quite impractical. At this meeting, one of the reviewers, Dr. Roy Albert of NYU, suggested they employ the more or less standardized approach we have already mentioned, viz., use a common vector for different elements in a given category, i.e., cesium chloride for soluble forms and the FAP vector for the insoluble forms. This idea was adopted quickly. It meant that exposure techniques would not try to imitate "real-world" situations for each radionuclide. Instead, radiobiological information would be sought using the large differences in dose and dose-rate to lung and other organs uncomplicated by the idiosyncratic properties of aerosols involving each element. The exposure of young adult dogs to ^{90}Y , ^{91}Y , ^{144}Ce , and ^{90}Sr in fused aluminosilicate took place from 1968 to 1970.

3. Results of the Lovelace Inhalation Program with Beta- and Gamma-Emitting Radionuclides

a. Single Exposures

We will skip some years of interim developments in order to review without delay some of the results of the long-term effort.

A summary of the work with ^{90}Sr was presented by McClellan et al. (1972) at the AEC-sponsored symposium on Biological Implications of Radiostrontium held at Davis, California. They reported the same large differences due to form inhaled as we have noted from earlier work; but they could go a few steps further. The relatively soluble forms were rapidly absorbed from both lung and gastrointestinal tract and were distributed to tissues much as after oral or intravenous administration. Effects were also similar, viz., hematopoietic damage early at high doses and neoplasms of bone and contiguous tissues at later times. By contrast, the relatively insoluble form was retained for long periods in the lung with slow translocation to the skeleton and the tracheobronchial lymph nodes. At high doses, the insoluble forms caused radiation pneumonitis and pulmonary fibrosis. No lung tumors were seen at this stage, but some were predicted.

McClellan went to considerable lengths to compare the pharmacokinetics of the strontium chloride inhaled to the strontium citrate injected intravenously in the Utah work. The whole-body retention was larger by up to 40% initially after the *intravenous* injection. This difference gradually decreased so that the retention factors were identical after fifteen hundred days. The reasons for the more rapid loss after inhalation were attributed to the clearance from the respiratory tract to gut. Nevertheless, inhaled soluble strontium that reaches the lung is rapidly absorbed therefrom. Differences between the behavior of inhaled *insoluble* strontium and injected strontium in the Utah experiment were large and continuous.

Several completed studies in rats appeared in the early 1970s. These included a comparison of inhaled and injected iodine, the transferability of ^{90}Sr -induced leukemia in Holtzman rats, niobium and zirconium oxide distribution and excretion, effect of temperature on antimony aerosols, and short side experiments with dogs.

As the program evolved, there were eight major dog experiments with young adult beagles: four with relatively soluble forms ($^{90}\text{SrCl}_2$, $^{144}\text{CeCl}_3$, $^{91}\text{YCl}_3$, and

$^{137}\text{CsCl}$) and four with relatively insoluble forms (^{90}Y , ^{91}Y , ^{144}Ce , and ^{90}Sr , all as FAP). Two additional major experiments, added in 1972, exposed immature dogs (three months old) and old dogs (eight to ten years old) to ^{144}Ce FAP.^(a) Small-animal work with the same purposes ran in parallel.

In 1975, repeated exposures were added for comparison of both metabolism and effects with single exposures.

Each experiment had roughly the same format, viz., a large group of animals was exposed and set aside for life-span study, while a smaller group was entered into a serial-sacrifice program to determine distribution and excretion over the long pull and to watch the development of histopathology. There were, of course, autoradiographic studies and many special determinations, some on animals in the regular progression, others by special additions.

A broad summary of the distribution data, which could be used for dose-response calculations, is shown in table 9.11. While not the very latest, these results (1979) are near enough to the end of our period of coverage to give a broad view of the experiments (Hahn et al. 1979a).

TABLE 9.11. Dose-Response Longevity Studies—Beta Emitters, Lovelace Foundation

Radionuclide and Form	Whole-Body Retention Effective Half-Life	Age at Inhalation Exposure	Organs Receiving Substantial Radiation Doses				
			Lung	Skeleton	Liver	Whole- Body	TBLN
<i>Beagle Dogs</i>							
¹³⁷ CsCl	30 days	13 months				++	
⁹¹ YCl ₃	59 days	13 months	++	++	++		
¹⁴⁴ CeCl ₃	284 days	13 months	++	++	+++		
⁹⁰ SrCl ₂	5-10 years	13 months		+++			
⁹⁰ Y FAP	2.6 days	13 months	++				++
⁹¹ Y FAP	53 days	13 months	+++				+++
¹⁴⁴ Ce FAP	≈200 days	13 months	+++	+	+		+++
⁹⁰ Sr FAP	≈400 days	13 months	+++	+			+++
¹⁴⁴ Ce FAP	≈200 days	3 months	+++	+	+		+++
¹⁴⁴ Ce FAP	≈200 days	8-10 years	+++	+	+		+++
<i>Syrian Hamsters</i>							
¹⁴⁴ CeO ₂	≈63 days	28 days	+++	+	+		
¹⁴⁴ CeO ₂	≈63 days	84 days	+++	+	+		+++
¹⁴⁴ CeO ₂	≈63 days	340 days	+++	+	+		+++
<i>Mice</i>							
⁹⁰ Y FAP	≈2.6 days	6-8 weeks	++	+			++
¹⁴⁴ CeO ₂	≈21 days	8-10 weeks	+++	+	+		+++
¹⁴⁴ Ce FAP	≈21 days	15-20 weeks	+++	+	+		+++
<i>Rats</i>							
¹⁴⁴ CeO ₂	≈85 days	12 weeks	+++	+	+		+++

FAP = Fused aluminosilicate particles.

TBLN = Tracheobronchial lymph nodes.

+ = Relative magnitude of dose received.

* ^{144}Ce , ^{90}Sr and ^{137}Sr as used in this test refer to ^{144}Ce in equilibrium with its daughter, ^{144}Pr , ^{90}Sr in equilibrium with its daughter, ^{90}Y , and ^{137}Cs in equilibrium with its daughter, $^{137\text{m}}\text{Ba}$.

Source: Reset from Hahn et al. 1979a.

(a) Cerium-144 refers to ^{144}Ce in equilibrium with its daughter, ^{144}Pr ; ^{90}Sr refers to ^{90}Sr in equilibrium with its daughter, ^{90}Y ; and ^{137}Cs is in equilibrium with its daughter, $^{137\text{m}}\text{Ba}$.

The variations in whole-body retention time and the dose to important organs, dependent to a large extent on retention time also, can be seen in this table. Also apparent are the larger retention in whole body and larger dose to lung with the insoluble forms; the lack of accumulation in lymph nodes of the soluble forms; the greater dose to skeleton from the soluble forms of ^{91}Y , ^{144}Ce , and ^{90}Sr ; and the greater dose to liver from the soluble forms of ^{91}Y and ^{144}Ce . While the whole-body retention half-time was markedly lower for both immature and aged dogs receiving ^{144}Ce FAP, the organs receiving substantial radiation doses did not change.

The results with hamsters, rats, and mice confirmed in general the findings in dogs but did not always agree quantitatively among themselves (see Snipes, Boecker, and McClellan 1983).

An illustration of the marked difference in dosage pattern, including total accumulated doses for the different radionuclides, all in insoluble form, is seen in figure 9.25. Naturally, the initial dose rates to lung vary in more or less inverse fashion to the order shown in figure 9.25, and, as shown in figure 9.26, these differences in dose rate are very large indeed.

FIGURE 9.25. Absorbed beta dose rate to the lungs of beagle dogs from various inhaled radioactive aerosols normalized to an initial dose rate of 100 rads/day (110 g lung). Lovelace work. (Redrawn from Hahn et al. 1979a.)

FIGURE 9.26 Patterns for accumulating 2000 rads total beta dose to the lungs of beagle dogs from various inhaled radioactive aerosols (110 g lung). Lovelace work. (Redrawn from Hahn et al. 1979a.)

A summary of the primary biological effects, the numbers of animals used, and other details of the eight life-span experiments in young adult dogs are given in table 9.12. Special mention should be made of the following:

1. Nasal cavity neoplasms were fairly common with the soluble compounds. Except for carcinomas of the nasal sinuses from radon, produced by radium in situ (chapter 1), such lesions are not common with inhaled alpha emitters. The greater penetrability of the beta particles may be the cause of the difference.
2. Soluble $^{144}\text{Ce Cl}_3$ caused neoplasms of nearly all tissues considered as potential targets. Liver problems were particularly notable with this isotope and form.
3. Only bone neoplasms appeared as a late effect of soluble strontium. Leukemia appeared in the one- to two-year period and bone marrow aplasia in the early period. Strontium seems to be different from the other elements tested.

TABLE 9.12. Observed Biological Effect in Longevity Studies of Beta Emitters Inhaled by Dogs (9/30/79)

Radio-nuclide and Form	Organ Receiving Major Radiation Dose	Number in Study (a)	Early Effects to 1 Year	Intermediate Effects 1 to 2 Years	Late Effects Over 2 Years	Current Age of Survivors (Years After Exposure)	Number Surviving
$^{137}\text{CsCl}$	Whole body	66	Marrow aplasia	—	Neoplasia—Miscellaneous organs	10.6-11.3	36
$^{91}\text{YCl}_3$	Skeleton Lung Liver	58	Marrow aplasia	—	Nasal cavity neoplasms Lung neoplasm	12.3-12.9	19

FAP = fused aluminosilicate particles.

(a) Original states "number of study."

Source: Reset from Hahn et al. 1979a.

4. As seen in studies discussed earlier, pneumonitis and lung fibrosis were universal early effects of the insoluble forms.
5. Later effects of insoluble forms were limited to lung and adjacent tissues for ^{90}Y , ^{91}Y , and ^{90}Sr , except for heart neoplasms with ^{90}Sr . Bone and liver were involved along with the respiratory tract with ^{144}Ce .
6. Some lung tumors spawned osteosarcomas.
7. The protracted irradiation from ^{90}Sr and ^{144}Ce is relatively more efficient in producing pulmonary hemangiosarcomas than less protracted patterns.

An especially notable finding in this long series of experiments was the occurrence of tumors in the mediastinum and vessels of the tracheobronchial lymph nodes with insoluble ^{144}Ce . As described many times, the very large calculated radiation doses to the lymph nodes draining the lungs have suggested use of this tissue as a critical organ in establishing maximum permissible exposures for inhaled insoluble radionuclides. (See, for example, Myers 1972 and chapter 16.) While there was plenty of evidence of effects, including complete necrosis of the lymph nodes, cancer seemed never to arise in these areas. (A few instances of invasion by tumors originating in other areas are known.) For this reason, among others, lymph nodes were never designated as a critical organ (cf. Myers 1972).

In report number XII on the toxicity of inhaled insoluble ^{144}Ce , Hahn and colleagues (1979b) describe primary tumors (hemangiosarcomas) of the tracheobronchial lymph nodes (TBLN) of dogs. They were not the most frequent tumor; primary lung tumors were the most frequently observed. Nevertheless, this occurrence removes a puzzling discrepancy from past work since it seemed unlikely that the TBLN would *never* be the site of a primary tumor, as had seemed to be the case. A concise published version was presented at the Hanford life sciences symposium in October 1979 (Hahn and Boecker 1980). There can be no doubt that the tumors are real and primary. Details for those animals that showed these tumors, as a late effect, are given in table 9.13. Note the enormous calculated radiation dose to lymph nodes and the relatively large dose to lung also. But note also (table 9.12) that many other effects and neoplasms occurred in the fifty-nine animals that had died after exposure to insoluble ^{144}Ce . This is even more striking when the wide range of effects seen is

TABLE 9.13. Dosimetric and Pathologic Data for Dogs That Died With Tumors Arising from the Tracheobronchial Lymph Nodes After a Single Inhalation Exposure to a Relatively Insoluble Form of ^{144}Ce

Dog Number	ILB ($\mu\text{Ci/kg}$)	To Death			Primary Cause of Death	Metastasis of TBLN Tumor
		Cumulative Rads to TBLN	Cumulative Rads to Lung	Days After Exposure		
208D	15	130,000	20,000	2396	Tumor-Mediastinum	Yes
467A	13	110,000	17,000	1763	Tumor-Mediastinum	Yes
326C	12	100,000	16,000	3280	Tumor-Mediastinum	Yes

reviewed, as in table 9.14. It appears that ^{144}Ce is the most indiscriminating of the radionuclides in the organs and tissues it chooses to affect.

Similar tables are shown in the annual reports for each experiment. Those for the soluble forms show some variety but less than that seen in table 9.14. The summaries for the insoluble substances tend toward more constancy of

TABLE 9.14. Summary of Deaths of Dogs Exposed by Inhalation to ^{144}Ce in Fused Aluminosilicate Particles (9/30/79)

Diagnosis	Number of Dogs	ILB's ($\mu\text{Ci/kg}$ Body Weight)	Survival Times (DPE)	Cumulative Dose to Lung (rads)
<i>Respiratory Tract</i>

diagnosis at death or euthanasia. With soluble strontium, bone neoplasms outnumbered all others, while with $^{91}\text{YCl}_3$ and $^{144}\text{CeCl}_3$ hematologic dyscrasias predominated, followed closely by carcinoma of the nasal cavity with $^{144}\text{CeCl}_3$. Yet, the number of other dyscrasias and lesions was considerable.^(a) With ^{90}Y , in contrast to other insoluble substances, a predominance of one effect was marked, viz., thirty-eight of forty-six cases died from radiation pneumonitis and pulmonary fibrosis (due probably to the high dose rate delivered by ^{90}Y). With ^{91}Y , forty of sixty-one cases had radiation pneumonitis and five had bronchioalveolar carcinoma. Insoluble ^{90}Sr showed thirty-four cases of radiation pneumonitis, sixteen pulmonary hemangiosarcomas, and eleven hemangiosarcomas of the heart out of seventy-four cases.

Even though the whole story is not yet told, these experiments to date indicate the very marked differences that can occur depending upon chemical form, not a new finding but one strongly reinforced by this work. *The experiments also isolated the contrasting effects of different elements, even isotopes of the same element.* That this latter occurs despite a relatively standardized system in which the aerosol parameters are essentially the same in each experiment bespeaks the importance of dosage pattern and other factors, such as energy, which are characteristic of the radioisotope in question. *These results alone are an argument for doing these long and expensive experiments.*

The experiments with inhaled ^{144}Ce in a relatively insoluble form in immature and aged dogs (see table 9.11) showed interesting similarities and contrasts to the young adults. With the immature dogs (ninety days of age at exposure), congestive heart failure was present in three of four dogs that died shortly after exposure (Boecker et al. 1979b). Also, pulmonary angiosarcomas occurred earlier and at lower radiation doses than in the animals exposed as young adults. No bronchioalveolar carcinomas had occurred at the time of reporting, but some were expected.

Other differences were seen with the aged dogs (Hahn et al. 1979c). Retention in the lungs was similar to that in young adults, but uptake by liver and skeleton was lower, especially in the latter. No hemangiosarcomas have developed to date in these animals, perhaps because the high dose needed to bring them about killed the older dogs with radiation pneumonitis. On the other hand, four pulmonary carcinomas have appeared, one of them causing the animal's death.

These differences, while not large, indicate, especially when combined with the experiments in rodents, that age at exposure can also play a role in the final results, at least with insoluble cerium. Since this work is less far along than the exposures of young adults, some modifications of the results may turn up in the future.

Cesium-137 has major health physics problems for handling as an aerosol. Because of its rather uniform distribution in the body, regardless of mode of entry, noted in earlier work, the Lovelace workers decided to administer it by intravenous injection. The results are reported in successive annual reports. They are not indicative yet of anything very special, viz., eleven cases of hematologic dyscrasia out of twenty-five exposed dogs that have died, and one squamous cell carcinoma of the maxillary sinus. The cumulative radiation doses to the whole body were from 690 to 2,200 rad in the twenty-five cases.

(a) There had already been work on cerium at Hanford.

b. Multiple Exposures

In general, there seems to have been considerable reluctance in the inhalation toxicology fraternity to enter upon long-term multiple exposure experiments with large animals. This is not surprising. Each single exposure is a fairly complex process. With hundreds of animals on line, simply keeping the single exposures up-to-date required large facilities and staff. Also, particularly in the earlier years, only limited amounts of the isotope of requisite purity were available. Handling large amounts at one time not only involved radiation hazards but was frequently not possible. It was quite different at Rochester, the home of the multiple-exposure experiment, where natural uranium was used for daily exposures five days per week. Supplies were ample and radiation hazards minimal.

Nevertheless, it was recognized that some occupational and many environmental exposures were either nearly continuous or in a series of single exposures. We have already seen that at Hanford Battelle undertook multiple inhalation exposures to transuranic elements. The Lovelace group introduced weekly exposures to ^{137}Cs -labeled FAP, ^{144}Ce FAP, $^{239}\text{PuO}_2$ in dogs, and $^{144}\text{CeO}_2$ in rats in the 1970s. (a)

The ^{137}Cs work (Boecker, Thomas, and McClellan 1975) involved twelve dogs each in groups receiving ten, twenty, or forty weekly exposures. The aerosol was insoluble and polydisperse, 1.5 to 2.0 μm , $\sigma_g = 1.5$ to 1.7. Average deposition percentages remained constant up to thirty exposures but fell off in the last ten exposures. As might be expected, a somewhat higher fraction of the body burden was found in the lung of the multiply exposed dogs. Autoradiographs showed that the ^{137}Cs remained associated with carrier particles for long periods after both single and multiple exposures. The most significant single difference in distribution and excretion was considerably longer retention after repeated exposures. Long-term whole-body retention ranged from twelve hundred to eighteen hundred days effective half-life compared to about four hundred days after single exposures. The result is a significant increase in cumulative radiation dose. No biological effect, including change in clearance rates from the lungs, was noted in this work since the observation period was not yet long.

A much longer-term multiple-exposure inhalation experiment was initiated in November 1973 using ^{144}Ce FAP. Exposures occurred once every eight weeks for two years. The retention was such that a fairly constant exposure to lung occurred. Although many of the animals are still alive, the results suggest that appearance of pulmonary tumors is delayed on the repeated exposure regime (Boecker et al. 1979a). For example, fifteen pulmonary tumors were seen in singly exposed dogs during the first twenty-two hundred days, while no pulmonary tumors appeared in the repeatedly exposed dogs. However, hemangiosarcomas and bronchioalveolar carcinomas began to appear later on. This reflects again the importance of dose kinetics in the temporal manifestations of effect.

Work with mice (Hahn, Lundgren, and McClellan 1980) showed a sparing of the life-shortening effect of $^{144}\text{CeO}_2$ in multiple exposures. *The protraction of dose had no effect on the total number of lung tumors seen or their time of development, i.e., total dose, not dose rate, seemed to be the important parameter.* This conflicts with our general knowledge of recovery and repair from exposure to low linear-energy-transfer (LET) radiation. However, it is consistent with some other work using beta-emitting radioisotopes. It may represent

(a) We will discuss the plutonium work in the following section.

a particular facet in a rather complex relationship between total dose and dose rate in radiation carcinogenesis as well as the fact that with internal emitters the dose never stops, as it does in experiments with external sources. It just varies in intensity. *The contrast between effects on life span and on carcinogenesis is consistent with other work on life-span shortening* (see chapter 4).

A repeated exposure study in rats was begun in 1976–1977, but the late results have not been seen.

4. The Alpha Emitters Come to Lovelace

With the enormous amount of work on plutonium, transplutoniums, polonium, radon and its daughter products, and radium already seen in several earlier chapters, it is hard to believe that still more could be needed. Yet it was, particularly around some of the problems of pulmonary radiotoxicology. The decision to emphasize light-water reactors and the uranium-plutonium fuel cycle (not an unmitigated blessing in this writer's view) and the consequent potential rise in amounts of plutonium and other transuranics needing storage, reprocessing and/or disposal brought ever more concern about the toxic effects of plutonium. The "hot particle" problem added much fuel to these concerns. We will discuss the problem itself in section V A below. Suffice it to say here that it was the hot particle problem that brought a new, fairly large research program on alpha emitters to Lovelace.

a. Monodisperse Aerosols

Kotrappa and Moss (1971) introduced a clever twist in the aerosol field. They used one of the devices developed for separating particles by size for characterization of aerosols into a method for preparing monodisperse aerosols. The device was Stöber's aerosol spectrometer, which is an aerosol centrifuge based on a spinning spiral. Large instead of small samples of a thermally degraded aerosol of FAP were collected on the metal strips on which the particles were deposited. Tyndall spectra plus electron microscopy and a Zeiss particle size analyzer showed good particle separation. The brass strip could be cut into sections depending upon the size range desired. After removal, washings, and transfers, the resulting solution could be made airborne in a Lovelace nebulizer. Count median diameters between 0.32 and 1.78 μm with geometric standard deviations no larger than 1.17 and usually lower were characteristic of the resulting aerosols.^(a) The best they could do was a geometric deviation of 1.03, and most had a somewhat larger range; however, it is common to consider aerosols with σ_g in the 1.1 range as monodisperse.

Kotrappa and Moss (1971) tried out the technique in animals with oxides of ^{238}Pu , ^{239}Pu , ^{241}Am , and ^{244}Cm . They measured respiratory deposition in a beagle dog and concluded that the technique could easily produce lung burdens well above the equivalent of a maximum permissible burden in man. They had thus solved one of the recurrent problems with monodisperse aerosols—insufficient quantities.

(a) This was only one of three methods used for preparing monodisperse aerosols at Lovelace (McClellan 1972). It was used the most because of its rather remarkable lack of multiplet formation (multiplets = result of coalescence of single particles into larger ones containing multiples of the single particles) and the amount of material it could produce. Further background can be found in Raabe (1970).

Kotrappa, Wilkinson, and Boyd (1972) presented a modification of the above procedure at the Hanford symposium on transuranics. This used a Lovelace Aerosol Particle Separator instead of the Stöber device. This is still a centrifugal method with an expanding spiral channel. A diagram of the device is given by Kotrappa et al. The resulting particles are, or can be, nearly spherical. It had some difficulty producing enough material for any large program in dogs using relatively low-specific-activity isotopes, such as ^{239}Pu . The authors suggest its most useful application might be with higher-specific-activity transuranics. However, further developments made it possible to use ^{239}Pu .

b. Initial Transuranic Experiments

Although the second paper cited above indicates that the development of the technique was specifically for transuranic elements, this was not quite the beginning of the major effort at Lovelace with alpha emitters. It was in 1974 that Tamplin and Cochran, and Tamplin and Geesaman (see section V A) launched the hot particle controversy as applied to the lung. The Lovelace people had begun exposure of dogs to transuranics before this time as described by McClellan (1972). However, it was not yet a major undertaking.

McClellan (1972) gives the status of the work with beagles using ^{241}Am and ^{244}Cm and comparison of their results with those on plutonium in several forms in the Hanford work. The *raison d'être* at this time was the need for work on these two transuranics in a large animal to extend the ideas developed from work with rodents. They confirmed, in the dog, the much greater transportability from lung of inhaled $^{241}\text{AmO}_2$, $^{244}\text{CmCl}_3$, and $^{244}\text{CmO}_{1.73}$ with transport to skeleton and liver. There was also considerable additional work on particle-size effects and some theoretical lung retention curves from monodisperse plutonium aerosols. Five proposed life-span studies with monodisperse aerosols and work with Syrian hamsters were described at this time (1972).^(a)

c. The Major Plan

Following the lines outlined by McClellan, a fairly elaborate plan evolved, but now with special additional emphasis on the hot particle problem. The monodisperse aerosol gave an opportunity to produce, at least initially, widely different local dose rates while maintaining reasonably constant average dose rates.

The relationship of these for ^{239}Pu and ^{238}Pu is shown in figure 9.27A, and the plan of the experiment is given in figure 9.27B.

Two monodisperse particle sizes were usually chosen for the work: $1.5\ \mu\text{M}$ and $3.0\ \mu\text{M}$ aerodynamic diameter, but with some work at $0.75\ \mu\text{M}$ also. Seventy-two dogs took part in the experiment with ^{238}Pu and 316 dogs and 480 Fischer 344 rats in that with ^{239}Pu , plus side experiments with hamsters, and recently the addition of immature and aged beagles as in the fission product work.

The Lovelace work became part of a grand plan. The Hanford experiments were using primarily polydisperse aerosols. Assuming other factors were reasonably comparable, this would produce a "smeared" dose as against a more discrete dose from the monodisperse aerosol.^(b) A third approach was work at

(a) Important other contributors to the monodisperse aerosol project were Drs. Otto Raabe and George Newton.

(b) The Lovelace people compared mono- and polydisperse aerosols in the same experiment to eliminate possible differences between the laboratories or at least to see if there were any, but the interlaboratory collaboration added a further dimension.

FIGURE 9.27A. Calculated dose relationships for the five planned dog longevity studies involving monodisperse aerosols of $^{238}(90\%)\text{PuO}_2$ or $^{239}\text{PuO}_2$. Local dose rate was computed in a $180\text{-}\mu\text{m}$ sphere of lung tissue (density = 0.22 g/cm^3). The calculation of average dose rate was based on a 110-g lung. Self absorption of alpha energy by the particles was ignored. (Redrawn from Muggenburg et al. 1979.)

FIGURE 9.27B. Schematic representation of the experimental design of longevity studies involving dogs exposed to different monodisperse aerosols of $^{238}(90\%)\text{PuO}_2$. Each cube represents one dog entered into the experiment at 12 to 14 months of age. (Redrawn from Muggenburg et al. 1979.)

Los Alamos with microspheres of plutonium oxide/zirconium oxide injected intravenously, which we will review in later sections.

The pharmacokinetics of the monodisperse aerosols does not seem to have been studied in depth since emphasis was placed in this work on biological effects. What information there is on distribution and excretion of the Lovelace monodisperse aerosols does not indicate notable differences in items such as initial deposition, clearance, etc. There did seem to be almost equal amounts in liver and skeleton, somewhat in contrast to some work in other laboratories.

It seems likely that the processes of lung clearance would gradually make the polydisperse aerosols more monodisperse and also break up or polymerize the monodisperse products so that initial differences would gradually disappear. However, this is not addressed in the Lovelace work we are considering.

The results of these experiments were reported in the same way as the work with fission products, including a report on each animal in the appendix to each annual report. Since the results bear heavily, though not exclusively, on the hot particle problem, we will hold review of the biological effects for that discussion (section V A).

5. Miscellaneous

a. Facilities and Personnel

By the end of the decade of the seventies, the Inhalation Toxicology Research Institute had over two hundred personnel and had broadened the scope of its activities to nonnuclear problems. The facilities at South Sandia Base were able to house essentially all of the programs and were quite extensive. An aerial photograph of the Institute's layout at the end of the 1970s is shown in figure 9.28A. Steps in reaching this stage appear in figure 9.28B and 9.28C.

FIGURE 9.28A. The Lovelace facilities in September 1983. It was by then the Inhalation Toxicology Research Institute (ITRI) and had diversified into many areas of inhalation toxicology. (Photos courtesy of Drs. Roger McClellan and Bruce Boecker, ITRI.)

FIGURE 9.28B. The Lovelace Hospital and Clinic in which the inhalation toxicology work began. The problems of using radioactive materials, particularly aerosols, in this facility made the need for a more isolated facility urgent.

FIGURE 9.28C. The Lovelace project in August 1963, not too long after the inhalation exposure work had been moved out to the Sandia Base. Note the single holding pond at the upper right. This held weakly contaminated water and utilized the strong evaporative power of the desert sun to reduce greatly the volume of material needing disposal. The project was referred to then as the "MEC-1013 Project" or just the "1013" Project.

The personnel roster has stayed relatively constant in the senior ranks. Bob Thomas went to Los Alamos in the midseventies to help with their radiation toxicology program. Otto Raabe went to the University of California at Davis in the late seventies. Otherwise the names attached to the various progress reports represent well the senior staff at Lovelace in the nuclear energy field. The institute has expanded greatly into general inhalation toxicology around the problems of energy generation. The presence of strong aerosol and biomedical effects groups made the transition practical and productive.

b. Aerosol Research

In addition to the activities we have already seen, the aerosol group was busy doing field sampling and characterization at industrial sites, studying effects of thermal history of the aerosol on its properties (see Hanford description, also Thomas, Walker, and McClellan 1971 and Thomas et al. 1973), devising special exposure chambers, and exploring basic properties such as the charge characteristics of aerosols.

Particular note should be taken of work spearheaded by Otto Raabe and George Kanapilly. Noting the fact that deposited particles seemed to undergo dissolution as well as transport *in vivo*, they engaged for some years in studies of dissolution *in vitro*. Kanapilly et al. (1973) devised a system whereby solvents flow past particulate material collected on a membrane filter. A simulant of blood serum was devised, and dissolution of $^{144}\text{CeCl}_3$ particles, ^{95}Zr - ^{95}Nb , and ^{90}Sr FAP particles was measured. In general, the rates *in vitro* were comparable to those *in vivo* so long as the proper simulant was used. This technique was very useful in predicting behavior *in vivo* and was used in conjunction with lung modeling activities. A special lung-fluid simulant was devised by Raabe and used by him in a large number of experiments.

c. New Species

In addition to rat and dog experiments already cited, there was much work with Syrian hamsters. This included distribution and excretion of ^{244}Am and approaches to estimation of ^{241}Am body burdens *in vivo* (Thomas 1970). Biliary excretion of ^{144}Ce was also measured in the Syrian hamster. Carrier effects in ^{144}Ce aerosols were described along with the ubiquitous problem of chemical state.

d. Modeling

Partly as an outgrowth of the aerosol work and partly from the work on distribution and excretion, the Lovelace group has been active in devising metabolic models. Particularly they have presented models that expand a bit on the ICRP lung model, which we will discuss in chapter 16. Also, lung morphometry has been studied by preparation of elegant casts prepared by infiltration of plastic.

Lovelace conducted a six-year project for the National Institute of Environmental Health Sciences (NIEHS) under an interagency agreement between NIEHS and the DOE. This project involved *in-situ* casting techniques (over thirty-eight thousand records of airway characteristics) in four mammalian species; respiratory tract characteristics in the same species (human, dog, rat, and Syrian hamster); and animal inhalation studies. A detailed final report of this work was presented by Yeh (1980); it gives deposition models for the four species and details of the research. Among the findings are a partial explanation

for the higher deposition in the right apical lobe of mammals and why the alveolar surface area of dog and man are very similar despite the difference in body weight. The dog has three times as many alveoli as humans. Also, the respiratory structures of the Syrian hamster resemble the rat's, but the hamster has more anatomical dead space and thus lower deposition than the rat. The report concludes that the ICRP lung model overestimates deposition.

e. Physiological Aspects

In addition to the huge amount of biological information produced in the long-term experiments, many special studies were undertaken. Among these are functional studies, particularly of pulmonary and cardiovascular function; relationships among the various respiratory parameters as lung damage progressed; pathogenesis of the many lesions found in the exposed dogs; and biochemical studies (see, for example, papers by Pfleger et al. [1975] and Pickrell et al. [1975] on pulmonary lipid composition, physiology, pathology, and connective tissue alterations from chronic lung irradiation from ^{144}Ce FAP).

f. Cytogenetics

The development of chromosome aberrations in lymphocytes cultured from the blood of exposed animals has been watched carefully by Brooks and his colleagues. With ^{239}Pu , for example, using the rhesus monkey, LaBauve et al. (1980) found what seemed to be a threshold for this nonstochastic effect at about 1,000 rad. There was other work along these lines, which we will have to omit.

Some work was done in the field of immunosuppression brought about by radionuclides in lung and lymph nodes and some in vitro studies of the interactions of cells with the materials of interest along the general lines of Sanders's work at Hanford.

g. Thorium

Relatively recently, the Lovelace group has begun work on both distribution and excretion, and eventually effects, of elements of the thorium-uranium fuel cycle. For the moment, it will be largely characterization of the materials and their aerosols.

6. Commentary

There is no doubt that the Lovelace work accomplished its original purpose of studying inhaled fission product aerosols fully and completely. There is far too much detail in the reports to ferret out any way or ways in which the results brought complete surprises or markedly contradictory conclusions to what might have been anticipated from the earlier inhalation or from the intravenous work. This was not expected. Quantitative differences are numerous and, of course, everything is much more certain. The much larger doses of beta radiation needed for production of lung tumors, as compared to the alpha emitters, is comparable to that seen earlier for bone tumors. The unique position of plutonium has been maintained.

As the work continues to unfold, more and more final conclusions can be drawn.

C. University of Rochester

1. Generally Speaking

The University of Rochester's Department of Radiation Biology and Biophysics (originally Atomic Energy Project) qualifies fully as a center for postwar work in pulmonary radiotoxicology. However, the emphasis and programs differ significantly from the research at Hanford and Lovelace Inhalation Toxicology Research Institute, which we have just reviewed. Only one experiment, the long-term uranium experiment,^(a) would qualify as a "king-sized" experiment of the dimensions seen at the above laboratories, plus Utah and Davis. Some of the work with radon was long-term but involved primarily small animals.

The reasons for this difference were partly the lack of space to spread out referred to earlier, partly a disinclination to add any more production-line type experiments (many of the personnel had been through the war years and desired other approaches), and partly the perceived need for one center with more concentration on the basic physiological and pharmacological processes underlying the work at all laboratories. After all, the new centers, manned to a considerable extent by people from Rochester, were doing many of the needed long-term effects experiments under quite favorable conditions. The status of Rochester as a center for graduate and postdoctoral training in the field, already alluded to, had a large influence on these trends also.

Thus, although the Rochester postwar program began as essentially an extension of the MED work, it gradually changed in emphasis. The postwar work was not only very versatile, with efforts involving many aspects of air pollution research, but it was carried on by relatively small clusters of investigators with a neat balance of the needs of the marketplace and "pure" science.

2. Aerosol Science

We have already reviewed briefly the many contributions from the Rochester group in the earlier section of this chapter devoted to this subject. For the record, we might list some of the major developments, including instruments that came out of the Rochester effort, in either late MED or postwar days:^(b)

- a. Cascade impactor applications
- b. Application of Wright Dust Feed
- c. Selenium coating for electron microscopy
- d. Efficiency of electrostatic precipitators
- e. Lauterbach aerosol generator
- f. Four-channel continuously recording monitor for airborne alpha activity (Morken and Wilson 1960)
- g. Oscillating thermal precipitator (Lauterbach et al. 1952)
- h. Point-to-plane electrostatic precipitator (Morrow and Mercer 1964)
- i. Aerosol centrifuge (Stöber 1967)
- j. Special exposure chambers for radon (see chapter 3 and section on Alpha Laboratory)
- k. Special exposure chambers for radioactive aerosols (see Alpha Laboratory)

(a) A very large experiment at Rochester on the effects of x rays on fertility in the dog paralleled the uranium experiment, but it is not part of the inhalation toxicology story we are reviewing.

(b) Most were referenced in the aerosol section of this chapter. Other references are added in this section.

- l. Multiple chambers for chronic inhalation studies (see uranium experiment)
- m. Interactions of aerosols with radionuclides (Mercer 1973)
- n. Charge characteristics of aerosols (Mercer)
- o. Role of particle size in deposition and retention (see all sections).

This is to name just a few. Other developments in aerosol science are quite basic to the field but beyond our scope here.^(a)

3. The Long-Term Uranium Experiment

This eleven-year-long chronic exposure experiment was described in some detail in the chapter on uranium (chapter 2). It was most like the "king-sized" experiments elsewhere of all the postwar work at Rochester. The exposures were to UO_2 dust, five days per week for up to five years. Deposition, retention, excretion, and short- and long-term effects were observed in a variety of species for up to six additional years, as well as during the exposure period. Perhaps the most cogent finding for the field of pulmonary radiotoxicology was the fact that radiogenic effects could be produced with inhaled insoluble uranium if one worked hard enough and long enough. Indeed, pulmonary cancers were produced in some of the dogs, a first. Comparable depositions in the monkey did not produce cancer, but there was serious and widespread fibrosis of lung and pulmonary lymphatics.

4. Work with Radon

Rochester worked in the field of radon and its daughter products in two, quite separate activities. Both of these are described in detail in chapter 3.

The first is the enunciation by W. F. Bale of the importance of the radiation dose from preformed radon daughters *inhaled* along with radon in the atmosphere.^(b) This was followed by experimental verification, which was done by Bale and Shapiro (chapter 3).

The other radon enterprise in the postwar years was the experimental work of Donald Morken with pathology done by J. K. Scott. This began with a small chamber for exposing mice to an atmosphere with low daughter product activity. The results (chapter 3) indicated acute toxicity quite comparable to a similar calculated dose from x rays. This was a surprising result in view of the usually tenfold or more greater effectiveness of alpha particles compared to low-LET radiation. It has stood the test of time, however, and indicates a low relative biological effectiveness for radon in acute exposures in the mouse at least.^(c)

Later, a larger unit that could accommodate more and a larger variety of animals was developed. The experiments, which included mice, rats, and dogs, involved measurements of life-span shortening, hematological changes, and histopathology. Daughter products could be present and the exposures could be single or prolonged. The results (chapter 3) might be characterized as expected,

(a) It might be added that Dr. Lucien Dautrebande, frequently referred to as the father of medical aerosols and the designer of many aerosol generators, spent several summers with the Rochester group and prepared his book on microaerosols (Dautrebande 1962) during these visits.

(b) Bale and John Harley at the Health and Safety Laboratories in New York share the honor of developing this idea, but Bale's written version appeared first.

(c) Later work with daughter products present indicated the usual extra effectiveness of alpha particles, but not necessarily as high as a factor of ten.

except for the total lack of lung tumor development. Some metaplasia was seen, but the lesion characteristic of uranium miners seemed extraordinarily hard to reproduce in this type of experiment under the conditions used.

5. The Alpha Laboratory

In chapter 8, we remarked on the desires expressed at the time of the development of the Utah project to have Rochester mount an inhalation program. We saw also that Rochester was a prime candidate for the fission product inhalation project that went to Lovelace. The reasons these did not develop at Rochester have already been reviewed. Nevertheless, both AEC Headquarters staff and many of the Rochester investigators were convinced that there should be a facility onsite capable of handling aerosols of radioactive materials of higher specific activity than the uranium facility could accommodate. Because of the long-standing interest in alpha emitters at Rochester, it was decided to develop a laboratory designed basically for work with aerosols, which would not require much shielding against penetrating radiation. The decision was made in the early 1950s, and the facility was called "The Alpha Laboratory."

A new research section was organized within the Division of Pharmacology known as "The Radioactive Inhalation Section." It was this writer's privilege to be its section head and to participate in most of the planning^(a) and its operations from 1952 until 1959, when he was called to be associate director for education of the project and associate dean for graduate studies of the school, a change made advisable by the illness of Dr. Henry A. Blair, the project director. Senior staff of the Radioactive Inhalation Section at the time of organization were Dr. Paul E. Morrow, a pharmacologist-toxicologist who began there an illustrious career, which has brought him international recognition; Dr. Frank A. Smith, a biochemist who has probably done more work on the biochemistry, pharmacology, and toxicology of fluorine and the fluorides than anyone else in America; Dr. Donald A. Morken, a brilliant engineering physics graduate with intimate knowledge of electronics who became interested in the radon problem and has stuck with it ever since, in addition to training numerous students in the electronics behind radiation measurements; and Robert H. Wilson, an engineer of remarkable creativity who took part in essentially every major engineering development of the Rochester Project. The planning board consisted of most of the section heads: W. F. Neuman, a biochemist; A. Rothstein, a biophysicist-cellular physiologist; J. K. Scott, a pathologist; J. N. Stannard, a radiation biologist-pharmacologist; R. W. Wilson, the engineer; T. T. Mercer (and they do not come any better), for aerosol problems; and finally, a representative from Health Physics. All was under the general direction of the Pharmacology Division head, Dr. Harold C. Hodge. There were about twenty other staff members. When, in 1959, the University established a new and separate Department of Pharmacology and selected Dr. Hodge to be its chairman, and Stannard went to other duties, part-time at least, a reorganization took place toward smaller academic-type clusters. Nevertheless, the laboratory continued its service functions until the alpha-emitter work had run its course.

Since the Alpha Laboratory was unique in design and different in purpose from some of the other installations, we will review its characteristics briefly.

(a) Some of the planning was already under way.

The laboratory was a service facility meant to accommodate a variety of experiments of different investigator groups simultaneously or in tandem, as needed. While there were a few more or less standard "dry boxes," there were many specialized ones built to order for the purpose at hand. The basic design had the usual separation of "Clean," "Low-Risk," and "High-Risk" areas (called "White," "Green," and "Red"). Entry to the latter was through a change room. Entry to the former was through a monitoring station. There was a small space available in the red area for storage of "hot animals," self-contained dish and cage washing equipment; a separate but connected hood room in the green area with low- and high-activity areas; a counting facility in the "cold" area; and detachable laboratory benches along the walls of the green area. The "dry boxes" were connected to the "high-risk" (red) area, but could be operated from the "low-risk" (green) area.

The services of monitoring, some counting, autoradiography dark room, cleaning, and some animal maintenance were provided by the basic staff. Anything more special fell upon the group doing the experiment.

The facility was really a "poor man's hot laboratory." There was no stainless steel, only easily cleanable and easily replaceable plastic or painted surfaces. The basic construction was wood and plywood, which saved thousands of dollars, but introduced, of course, a fire hazard far above the usual stainless steel and concrete installation. To minimize the fire hazard, all heating was done by electricity or steam. All electrical circuits were fused at amperages only slightly above the load to be applied.

The light construction could be employed because only alpha emitters were to be used. (Even so, some of the aerosol generators required shielding, as did some of the primary stock sources.)

Protection depended entirely upon an ingenious and elaborate system of ventilation. Pressure gradients, as in all good hot laboratories, were always from low-risk to high-risk areas with the final exhaust going through Cambridge Absolute Filters to a stack with continuous monitoring. Because of the extreme importance of maintaining the pressure gradients, every important ingredient in the system was installed in duplicate. Pressure-sensitive sensors brought the duplicate unit into operation before the overall pressure gradient could change appreciably. Backing up all of this was a propane-operated motor generator set which would switch in automatically in case of power failure, even if only one phase of the three-phase electrical input should falter. In many years of operation, there was never an instance of failure of this ventilation system.

The details of the laboratory's design, considered unique in its ability to use inexpensive materials and to operate in a populous area on a university campus, are described in a series of University of Rochester Project Reports cited in the bibliography (R. H. Wilson et al. 1955; Smith, Della Rosa, and Casarett 1955; Morrow and Casarett 1955; Rothstein and Hayes 1957; Whipple et al. 1955; Morken and Morrow 1956).

Other developments were protective clothing of special design and self-contained breathing apparatus, the latter developed by Scott Aviation Corporation;^(a) also, a special neoprene glove for the dry boxes, which provided high tactile sensitivity without compromising integrity of structure (Wilson UR-265). A picture of the inner corridor (high-risk area) with workers in full protective

clothing and a view of the low-risk (green) area are shown as figure 9.29A and 9.29B. A general floor diagram of the facility is shown as figure 9.30.(a).

FIGURE 9.29A. (Right) View of inner corridor of high-risk (red) area of Alpha Laboratory at the University of Rochester. Personnel are wearing full protective clothing and self-contained breathing equipment. The small tank on the latter could be supplemented by air under pressure from a quick disconnect plug in the ceiling. Note the communication cord is integrated loosely with the air hose.

(a) These pictures and diagrams are presented primarily because we have not viewed the facilities and needed personnel protection of a radioactive inhalation laboratory before. All of the installations have the same basic problems and similar ways to meet them, usually at higher cost because of the need for stainless steel and the like.

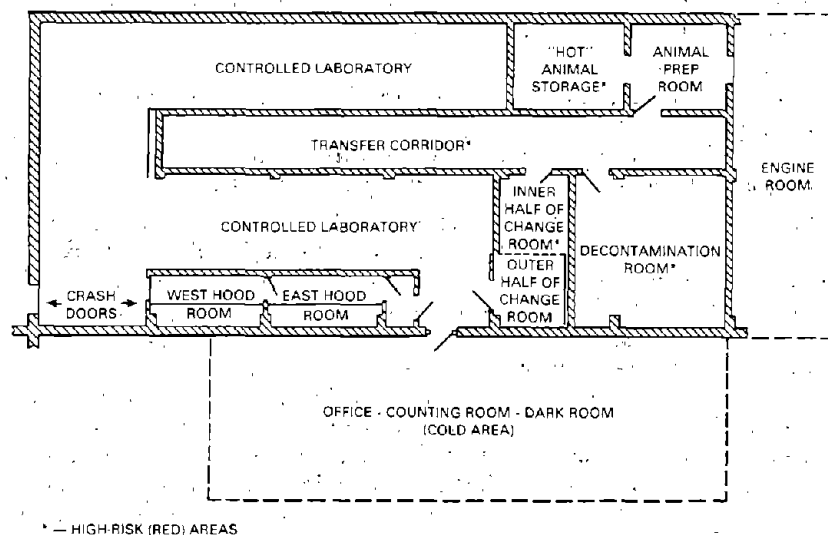

FIGURE 9.30. Floor plan of Alpha Laboratory. The controlled laboratory area is a low-risk but not a "cold" area. The high-risk (red) areas are marked with an asterisk. (Redrawn from R. H. Wilson et al. 1955.)

The specialized dry boxes varied from time to time. Typical are the original radon exposure units for small animals (see chapter 3); a sophisticated system for separating inhaled from expired air columns in the dog and measurement of both radioactivity and respiratory parameters remotely (Morken and Morrow 1956); a versatile unit for exposing animals to radioactive dust (Rothstein and Hayes 1957); nose-only exposure unit for polonium (Casarett 1964a); and others. We will review results of their use in subsequent sections.

There were, in addition, special design metabolism cages for keeping dogs in the high-risk area for short periods immediately after exposure (Morrow et al. 1967), special tongs for handling "hot" animals, etc.

The facility was used primarily for work with polonium, plutonium, and the radon experiment, which was next door but which shared some components. Later on, beta emitters such as ^{59}Fe , ^{192}Ir , and others were added, but not all such work was done in the alpha facility. The acquisition of two Air Force trailers left over from field work that we will see in chapter 14 expanded the facilities. One trailer was fitted out with well-counters and another was conveniently adapted to animal storage.

6. Inhalation of Polonium-210

In chapter 4, we reviewed the bulk of toxicological research on ^{210}Po . This included the fairly recent idea that the ^{210}Po in tobacco smoke might be a contributory, even a primary, factor in producing lung cancer in cigarette smokers. We did not consider in chapter 4 the MED or postwar work at Rochester on inhalation of ^{210}Po .

This work was conceived and done primarily to determine of the behavior and effects of this radionuclide after inhalation:

- a. for comparison with plutonium,
- b. because most of the significant dose from radon daughter products comes from isotopes of polonium,
- c. because polonium was still a potential industrial and environmental pollutant (in static eliminators, nuclear energy operations, etc.).

It was done well before the tobacco smoke possibility had been enunciated. The levels used were considerably higher than those found in tobacco smoke.

The Rochester work was led off by intratracheal injection of a freshly neutralized polonium solution in rats. This was first described in a project report by Thomas and Stannard (1956) and in detail in the *Polonium Supplement*^(a) (Thomas and Stannard 1964). This was paralleled by a comparison of ^{210}Po colloid with ^{210}Po -tagged silver particles given intratracheally to rabbits by Morrow and Della Rosa (1956) and a published paper (Morrow and Della Rosa 1964).

The experiment with rats was in three parts, short- and longer-term distribution after a single dose, and distribution and excretion after multiple intratracheal injections. The shorter-term distribution study went to sixty-two days, the longer-term distribution study to over four hundred days. Of considerable interest is the rapid loss from lung, the tendency toward a long period of constancy in the blood content, and widely different loss rates from different tissues. Kidney had the longest retention half-time, with liver, spleen, and gastrointestinal tract about one-third as long. These were all longer than after oral or intravenous intake.

On the multiple-dose regimen (one dose each two weeks for a total of five exposures), distribution and excretion were not the same as after a single instillation. The differences are indicated in figure 9.31A and B.

The work with the rabbit extended to thirty days. It demonstrated again rapid loss from lung and considerable accumulation in kidney. The most striking difference between rat and rabbit was in the urinary excretion rate. Whereas only about 1% of the dose appeared in urine after eight days, and only 2% after seventy days in the rat, the rabbit excreted 18% in eight days and 30% in the urine in thirty days. This species difference has been seen also after intravenous administration (chapter 4) and represents a fundamental difference in the handling of polonium. Tissue distribution patterns were similar in the two species.

Two metabolism experiments after inhalation of aerosols were done in the Alpha Laboratory following the intratracheal work. First reported was work using the large chamber described by Rothstein and Hayes diagrammed in figure 9.32 in which many animals were exposed "whole body," i.e., in a complete enclosure (Berke and DiPasqua 1957, 1960, 1964).

The second inhalation experiment was a "nose-only" exposure in rats by L. J. Casarett (1964a), which harked back in part to work done in his Ph.D. thesis. The idea of contrasting exposure modes was to determine what role the licking of fur and contamination of the head might have on total body burden. (This seems to be one of the few back-to-back experiments where this common dilemma of aerosol exposures was attacked directly.) The aerosol used by Casarett was quite small ($0.34\ \mu\text{MMD}$, $\sigma_g = 2.24$). Mean deposition was apparently higher in the nose-only experiment than in the chamber experiment and more

(a) Supplement 5 to *Radiation Research*, see chapter 4.

like figures for the same sodium chloride vector in dog and man. The tissue distribution of the deposited material was almost exactly the same with the two types of exposure.

Both inhalation experiments showed tissue distributions that were qualitatively different from those observed after intratracheal injection. Some of the difference may be due to the fluid introduced into the lungs by the intratracheal injection, which made their weight as much as 100% above that of animals that had inhaled the material. However, the differences were not limited to the respiratory tract. These confirm again the validity of doubts held concerning the use of intratracheal instillation as a surrogate for inhalation, at least for metabolism experiments. An example of the differences between routes is shown in table 9.15A and B.

TABLE 9.15. Distribution of ^{210}Po to Tissues

A.				
Intratracheal Injection Versus Inhalation-30 Days After Administration				
Tissue	Percent Dose		Percent Body Burden	
	Int.(a)	Inh.	Int.(a)	Inh.
Lung	11.1	5.9	35.8	42.7
Kidney	5.8	1.5	18.1	13.0
Liver	3.2	3.5	9.9	5.3
Spleen	1.2	0.35	3.9	3.5
Carcass	5.5	2.0	15.1	16.3
Blood	6.2	2.0	19.2	21.1

Meanwhile, the team of Berke and DiPasqua was conducting multiple inhalation exposures in the rat (1960). This was to check the ideas already developed from intravenous injection work (chapter 4) and intratracheal instillation (Thomas and Stannard 1956, 1964), which indicated different tissue distributions

and different biological elimination constants when materials were accumulated in several exposures. Fifty rats were used with ten consecutive daily exposures of five hours each. The postexposure interval was fifty-four days.

The results as given are tied to their bearing on maximum permissible air concentrations and calculations of maximum permissible exposures and do not present an overt comparison of the metabolism on the two regimens. The authors point out that the lung burden rises linearly with time, with the equilibrium time calculated as 185 days. This is, of course, much longer than after a single exposure. While the data are useful for predicting accumulation from multiple doses, the period of observation is probably too short to allow the appearance of any real differences in metabolism, even if the authors had searched for them.

Detailed and exhaustive autoradiography was done on tissues from the rabbits receiving ^{210}Po intratracheally (Casarett and Morrow 1964) and the rats receiving it by inhalation (Casarett 1964b). The findings are comparable to those of Sanders at Hanford that we discussed earlier insofar as the role of macrophages is concerned. This work preceded that of Sanders. In fact, it was Casarett who, using several routes of administration, first described in detail the phenomena of dissolution of the large aggregates ("stars") of polonium as a function of time in the tissues (Casarett 1956, 1964b; also his M.S. and Ph.D. theses). This followed in more elegant fashion a lead from a twenty-four-hour experiment described by Gallimore, Boyd, and Stannard (1954).

The autoradiographic work goes far beyond what we can report here. It made clear that material entering by the lung was removed largely by phagocytosis and that solubilization of the colloids by macrophages and/or lymphatic elements played an important role. Despite being a nominally "soluble" compound, there was little evidence of direct passage of polonium from lung to the vascular system because of its colloidal nature as a polonium hydroxide. The autoradiograms give ample evidence of adherence of the material to bronchiolar and other surfaces and the marked irregularity of the deposition and subsequent movements. They emphasize how crude any early-time lung dosimetry calculations must perforce be. Fortunately, the progressive disorganization of the sunbursts during transport and clearance, an outstanding contribution of this work, can be interpreted to mean that eventually a more regular, less punctate pattern develops so that lung dosimetry for later times may be more realistic than for the early periods after deposition.

As the facilities of the Alpha Laboratory came into fuller use, it was possible to expose dogs to polonium aerosols on a sodium chloride vector. For these experiments, measurements could be made of the inspired and expired concentrations, of the respiratory characteristics of each animal, and many correlations could be made. This utilized the apparatus, locally known as the "retention rig," developed by Morken and Morrow (1956) and described also by Morrow and Casarett (1955). This depended in turn on a wireless transducer pneumotachograph described by Morrow and Vosteen (1953). A schematic diagram of this apparatus is shown as figure 9.33.

The results in terms of distribution and excretion were described first in a project report (Smith et al. 1960) and a year later in the open literature (Smith et al. 1961). The exposures were single and brief and involved six dogs. Deposition averaged about 64%, in excellent agreement with deposition in man of the same aerosol containing the vector only (Morrow et al. 1958), but considerably higher than in the rat. Clearance showed an initial rapid and later slower phase as in

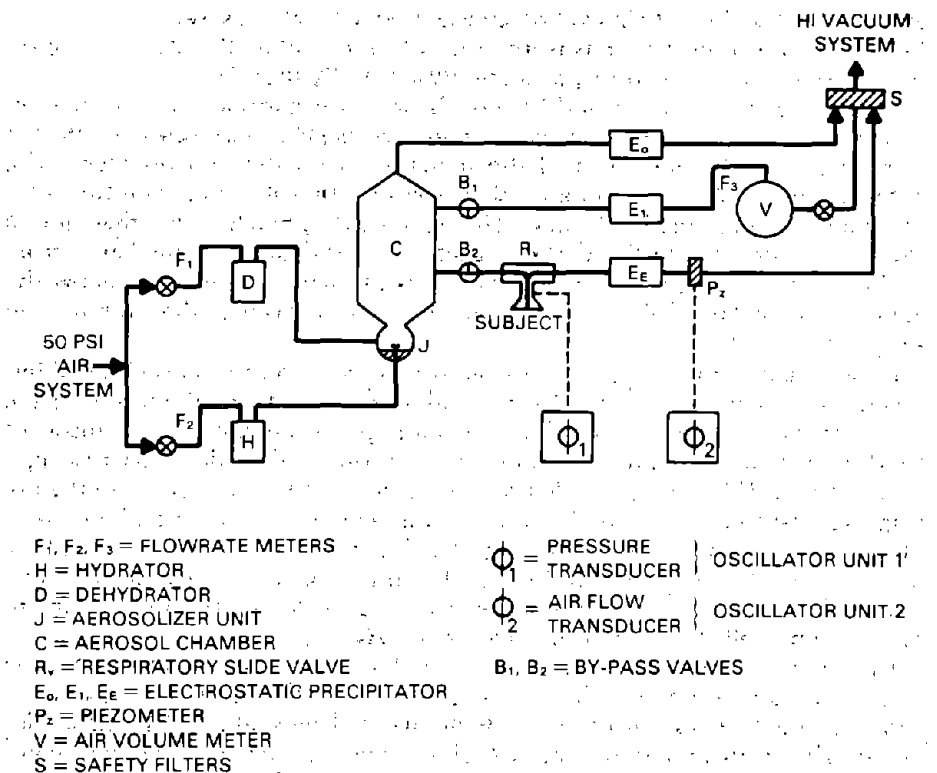

FIGURE 9.33. Schematic of retention apparatus developed at Rochester. (Redrawn from Morrow and Casarett 1955.)

the rat. The principal route of excretion was via the gastrointestinal tract. Exponential kinetics governed most of the loss patterns. While the tissue distribution patterns seem similar to those seen in the rat, the reliability of these data is much greater since the amount deposited is known by direct measurement for each dog. An interesting finding was the amount in the pelt, as much as 50% of the dose by 149 days—mostly in the hair follicles. (This could not have been from deposition on the fur, because the exposure was nose-only in the retention apparatus.) Clearance from the whole body seemed to be governed primarily by the rate of lung clearance.

Examination of long-term effects was possible in only a few experiments with rats. No long-term effects studies of inhaled polonium were done with dogs.

The first demonstration of lung cancer induced by ^{210}Po was contained in a quarterly report of the Atomic Energy Project (Scott and Thomas 1957). Two of fifteen rats developed squamous carcinoma 5 and 15 months after intratracheal injection. An extension (unpublished but quoted in the literature) showed production of six of these lesions in a group of forty-seven rats. The times were from 66 to 126 weeks after exposure.

Ten years later a true inhalation effects study was reported. The exposure chamber was the "whole-body" type described earlier. There were three exposure levels with fifty rats per level, and the postexposure period ran to 280 days.

The published report was produced by Yuile^(a), Berke, and Hull (1967). An easy summary of the results is contained in the abstract of their paper, which is reproduced below:

Inhalation by three groups of rats of NaCl aerosols with small amounts of Po^{210} added produced initial lung burdens of 0.15, 0.05, and 0.02 μCi . After 280 days, resulting accumulated lung doses were 538, 202, and 71 rads, respectively. Life span of the highest dose group was shortened, with 87% of the animals dying within one year after exposure, compared to 35% for controls and the other two experimental groups. Increased incidence and severity of acute pneumonia was the chief cause of the high mortality. Radiation changes in the lung were seen only in animals exposed to the highest level of radioactivity. No primary lung tumors developed in control rats, but 41 were found in 288 exposed rats dying spontaneously during the 96-week experiment. Squamous cell carcinoma was the commonest tumor type, accounting for 55% of the total number found. Over 70% of the squamous cell tumors occurred in rats exposed to the highest dose of Po^{210} , and many were early lesions associated with radiation injury. Pulmonary adenomas were seen only in rats exposed to low and medium doses. The highest dose appeared to be effective in preventing mediastinal lymphomas. (Yuile, Berke, and Hull 1967).

Not obvious from this abstract is the large number of deaths from chronic and acute pneumonia, a chronic problem in this and all other ordinary rat colonies. A picture of the spread in causes of death and the distribution of tumors by dosage level is shown in table 9.16A and B.

TABLE 9.16A. Summary of Pathological Findings After Polonium-210 Inhalation Excluding Neoplasms

Po^{210} Exposure Level	Total Number of Rats Exposed ^(a)	Age Range at End of Experiment (weeks)	Number of Spontaneous Deaths	Significant Nonneoplastic Pulmonary Lesions (% of rats dying spontaneously)			
				Chronic Pneumonia	Acute Pneumonia	Radiation Changes	Epithelial Metaplasia
Control 0 μCi	147	87-100	88	23	25	0	4
High 0.15 μCi	119	106	119	21	65	32	17
Medium 0.05 μCi	129	95-100	98	22	50	0	9
Low 0.02 μCi	132	89-91	71	25	45	0	4

(a) Dr. Charles Yuile had taken over the histopathology work done by Dr. J. K. Scott after he went to the Lovelace Foundation.

Quite obviously, these doses of polonium produce significant changes in lung, but unequivocal radiation changes and frank tumors are not overwhelming. Superficially this looks as though changes from polonium are less pronounced than those from plutonium (see studies elsewhere already reviewed). However, the period of observation was relatively short and the radiation doses relatively modest compared to the enormous doses we have become accustomed to in the dog experiments done with plutonium. Indeed, it appears that polonium is a moderately potent pulmonary carcinogen, either primary or secondary.

7. Inhalation of Plutonium

Inhalation work with $^{239}\text{PuO}_2$ began at Rochester in 1958. The facilities of the Alpha Laboratory were used for exposing dogs via the retention apparatus with the intent of measuring deposition more precisely and performing an intensive autoradiographic investigation of the tissues of the respiratory tract. The first report of results (except for in-house progress reports) came out at the Oxford symposium on Inhaled Particles and Vapours, March-April 1960 (Morrow and Casarett 1961). There were twenty-one experimental measurements in seventeen dogs using in-vivo counting for some of the points. The exposures were single. The aerosol characteristics varied from 1.7 $\mu\text{Ci/l}$, count median diameter 0.24 μ , σ_g 1.81 for the first seven exposures to 0.9 $\mu\text{Ci/l}$, count median diameter 0.70 μ , σ_g 1.77 for the balance of the exposures.

With the benefit of precise measurement of inhaled and exhaled air concentrations, deposition could be calculated with considerable confidence. With the small-sized aerosol, mass deposition was 56%, whereas it was 88% with the larger particle size aerosol. It seemed not to be related to the measured respiratory parameters within the range of this work. (It is, of course, impossible to train animals to hold their breath, take a deep breath, etc., which has made possible much of the information in humans on the role of respiratory parameters on deposition.)

A size analysis of the particles retained in the lung was performed, including the relative numbers of particles in various anatomical regions of the lower respiratory tract. The smallest particles were retained the longest. Excretion was largely in the feces, as expected.

The autoradiographic work showed very clearly that all known mechanisms of lung clearance were operable. Of special interest are autoradiograms of plutonium in the peribronchiolar lymphatics and an excellent illustration of the constantly frustrating difference in content of closely adjacent lymph nodes. (How can we ever decide what fraction of the lymphatic system is involved in chronic low-dose exposures and therefore what weight to assign to it for dosage calculation? Examples of these facts are shown in figure 9.34A and B.)

A more extensive inhalation study with plutonium (Morrow et al. 1967) involved twenty-two dogs. It was built upon the first one and includes some of the same animals. Plutonium-238 was used as was ^{239}Pu . Among other things, the problems of radiochemical analysis for plutonium were reexamined and new procedures adopted based on work of Toribara and colleagues (Toribara, Predmore, and Hargrave 1962; Toribara, Morken, and Predmore 1962). Emphasis was on clearance kinetics and mechanisms and on the early pathologic effects.

Clearance seemed to be biphasic and exponential to time with biological half-times of one and four hundred days. Bronchial lymph nodes and lung carried 95% of the body burden.

FIGURE 9.34A. (Right) Autoradiogram of lymphatic vessel and lymph nodes demonstrating the distribution of plutonium oxide dust particles in the dog—peribronchiolar lymphatics containing plutonium particles. (At least fifty-two particles are registered in this field.) (From Morrow and Casarett 1961. Reprinted with permission of Pergamon Press, Ltd., Elmsford, New York, copyright 1961.)

FIGURE 9.34B. (Left) Autoradiogram of lymphatic vessel and lymph nodes demonstrating the distribution of plutonium oxide dust particles in the dog—lymph nodes illustrating variable content of plutonium. (From Morrow and Casarett 1961. Reprinted with permission of Pergamon Press, Ltd., Elmsford, New York, copyright 1961.)

However, gonads appeared to receive significant radiation doses, raising again the question that came up in the early Hanford work as to the possibility of genetic changes. On the other hand, liver doses were quite low, in contrast to many other experiments we have seen.^(a) Similarly, relatively little plutonium was transported from lung to bone. These phenomena demonstrate the marked difference between inhalation and other routes of entry insofar as tissue distribution is concerned.

Kinetics of excretion were examined in depth and the presence of power-function-of-time kinetics reaffirmed. This has important bearing on the bioassay procedures of the past and present (chapter 7, 16). The authors engage in a detailed analysis of the excretion data and just how they do and do not fit the formulations of the day. Because of the relatively exact knowledge of deposition,

(a) It should be remembered that this work was well under way when the large efforts at Hanford and Lovelace came up to full speed, and it served as an important resource for these.

individual excretion curves could be drawn for each dog (Morrow et al. 1967, figure 10). Each one fitted power-function kinetics, but not with the same exponent.

Of considerable interest are the finding of progressive lymphopenia, beginning as early as two months postexposure, and focal pulmonary fibrosis. More complete information had to await further work, however.

The story was completed insofar as Rochester work was concerned with an experiment using both ^{238}Pu and ^{239}Pu . This extended out to 468 days after exposure (Yuile, Gibb, and Morrow 1970). There were nineteen dogs exposed to ^{239}Pu and six to ^{238}Pu . Doses ranged from 0.1 to 14.4 μCi initial lung burden of ^{239}Pu , and 11.4 to 181 μCi of ^{238}Pu . Since by this time the Hanford work was coming to fruition and being published extensively, there was much opportunity for comparison of results. As in other cases, the Rochester work emphasized mechanisms and, because the finding of early and constant leukopenia turned up in the Hanford dogs also, an extensive hematological study was included.

A grading system for the histopathology was devised for both lung and lymph node changes, and thus the degree of effect could be correlated with dose. Beginning at about 2,000 rad calculated dose, the radiation pathology in lungs rose steadily with dose up to about 15,000 rad (figure 9.35A). The lymph nodes showed no changes until radiation pathology was evident in the lungs. The development of damage from that point on correlated very poorly with calculated total dose to the lymph nodes. However, correlation with the alpha dose rate was as good as the correlation between total dose and lung damage. This unusual and most interesting finding is depicted in figure 9.35B.

FIGURE 9.35A. (Left) Degree of radiation changes in lungs and lymph nodes graded on scale of 1-5, following $^{239}\text{PuO}_2$ and $^{238}\text{PuO}_2$ inhalation, related to accumulated lung dose in rads. (Redrawn from Yuile, Gibb, and Morrow 1970. Reprinted with permission of Academic Press, Inc., Orlando, Florida, copyright 1970.)

FIGURE 9.35B. (Right) Degree of radiation changes in tracheobronchial lymph nodes graded on scale of 1-5, related to mean dose rate to lymph nodes in rad per day after inhalation of $^{239}\text{PuO}_2$ and $^{238}\text{PuO}_2$. The two $^{239}\text{PuO}_2$ points which appear lower than the general trend are regarded as unreliable. (Redrawn from Yuile, Gibb, and Morrow 1970. Reprinted with permission of Academic Press, Inc., Orlando, Florida, copyright 1970.)

A correlation with dose rate was unusual with alpha emitters at this time. In general, a large portion of the biological damage from alpha particles was considered to be irreversible, and dose rate effects small compared to low-LET radiation.^(a) This is discussed by Yuile et al., but they could muster no ready explanation for this apparent exception to a maxim of radiobiology. The phenomenon has been described in the work from other laboratories (see chapter 1) using human data in effects of ^{224}Ra that indicated increased effect with protraction. It seems quite unlikely that it is a trick of the data for this particular experiment. Thus, for the present, we must accept it as it stands and hope an explanation can be found in future work.

The other key finding in the Rochester plutonium pathology work concerns the origin of the leukopenia. On the basis of the extensive autoradiographic studies of the deposition and localization of plutonium, the investigators conclude that the leukopenia cannot arise from radiation effects in hematopoietic tissues, the usual mechanism with external penetrating radiation. They suggest instead that the radiosensitive small circulating lymphocytes receive their radiation damage during transit of the lungs and adjacent lymphatics. Since nearly every small lymphocyte passes through the lungs and recirculates rapidly between blood and lymph via nodes and spleen (see discussion in cited references from the literature), there is ample opportunity for the alpha sources to irradiate them and thus initiate cell destruction.

Little is said in this work about metaplasia, lung-tumor development, and the like. Obviously, the experiment was not of sufficient duration to provide reliable incidence data for these processes. It was not intended to, for the work at Hanford and Lovelace was covering the longer-term area adequately. No need was seen to expend animals, money, and time at Rochester to go beyond the probing into the specific problems and mechanisms we have already seen.

8. Miscellaneous Experiments and Elements

Rochester was considered throughout the existence of the AEC as a prime resource for investigating new and unexpected toxicology problems. When a new substance or radionuclide appeared about to assume practical importance, the Rochester group was frequently asked to advise (as soon as possible, of course) on any potential toxicity problems that might arise should the substance go into routine use. Some of this extended into the inhalation toxicology effort. As a result, a rather miscellaneous group of elements and compounds were investigated on request. Fortunately, in nearly every case, information of importance to the basic fabric of pulmonary radiotoxicology was frequently a by-product of these "command performances." Most of these reports were in the form of communications to Washington and are not available for general use now, but several are cited below.

Some of the staff from the radioactive inhalation program became involved in work concerning field releases of both plutonium and fission products, as we will see in chapter 14. By-products of the problems encountered in this work stimulated some additional laboratory investigations. These appeared in the project reports. Some were published. Some rested as essentially "memos to the files." Finally, there was much work done only because the investigator had an

(a) There are now many reports of enhancement of effect by protraction of alpha dose. Their explanation may lie in factors other than cellular recovery phenomena.

idea he wanted to check on, and the work fitted easily into the program. Many of these bore on lung clearance processes. By using a convenient isotope, data could be obtained with relative ease.

In toto, these miscellaneous efforts produced useful and interesting information. The following are samples:

1. *Metabolism of Thorium-230 (Ionium) Administered by Intratracheal Injection to the Rat* (Thomas 1957)
2. *Retention and Fate of Iridium-192 in Rats Following Inhalation* (Casarett et al. 1960)
3. *The Metabolism of Indium after Administration of a Single Dose to the Rat by Intratracheal, Subcutaneous, Intramuscular and Oral Injection* (Smith, Thomas, and Scott 1960)
4. *The Distribution and Excretion of Thallium-204 in the Rat, with Suggested MPC's and a Bioassay Procedure* (Lie, Thomas, and Scott 1960)
5. *Alveolar Clearance in Dogs after Inhalation of an Iron-59 Oxide Aerosol* (Gibb and Morrow 1962)
6. *Deposition and Fate of Inhaled Iron-59 Oxide* (Casarett and Epstein 1966)
7. *The Metabolism of Inhaled Mercury Vapour in the Rat Studied by Isotope Techniques* (Hayes and Rothstein 1962)
8. *The Excretion of Volatile Mercury by Rats Injected with Mercuric Salts* (Clarkson and Rothstein 1964)
9. *The Clearance of Uranium Dioxide Dust from the Lungs Following Single and Multiple Inhalation Exposures* (Morrow, Gibb, and Leach 1966)
10. *Measurement of ^{212}Pb Loss Rate from Human Lungs* (Hursh and Mercer 1970)
11. *Inhalation Studies of Uranium Trioxide* (Morrow, Gibb, and Beiter 1972)
12. *Effect of SO_2 on Lung Clearance of TiO_2* (Ferin and Leach 1973)
13. *Experimental Inhalation of Metallic Silver* (Phalen and Morrow 1973)
14. *Intramuscular Retention of UO_3 and UO_2* (Beiter, Gibb, and Morrow 1975)
15. *Studies on Tantalum Dust in the Lungs* (Bianco et al. 1974)
16. *The Uptake and Retention of Insufflated Tantalum in Lymph Nodes* (Kilpper et al. 1976)

9. Mechanisms and Modeling

We have intimated throughout this section that the Rochester work was especially oriented toward the physiological and pharmacological mechanisms underlying all problems in inhalation toxicology, especially pulmonary radiotoxicology. The literature of the field is huge. Yet, we can look briefly at some of the high points.

Local, national, and international work was drawn upon to prepare a number of definitive reviews, which have been and continue to be extremely useful. Quantitation was emphasized wherever possible. With T. T. Mercer down the hall, few opportunities for formulation of relationships were lost. One of the most outstanding among these was the development of a new and much more sophisticated model for respiratory-tract deposition, clearance, and general characteristics to replace the simple model used in the 1950s and early 1960s (see chapter 16). Paul Morrow was asked to head a Task Group on Lung Dynamics of the International Commission on Radiological Protection working under its Committee 2. Tom Mercer joined him so that two of the five members came from Rochester.^(a) The resulting publication (Task Group on Lung

(a) The others were David V. Bates, Royal Victoria Hospital, Montreal; Birney R. Fish, Oak Ridge National Laboratory; and Theodore F. Hatch, University of Pittsburgh Graduate School of Public Health.

Dynamics 1966) was a quantum jump in quantitation and sophistication from the previous model. With a few modifications, it is now the official ICRP model and has been adopted for U.S. practices. It is a keystone in radiation protection planning. We will review it further in chapter 16. Suffice it to say here that the emphasis at Rochester on getting solid data and ideas on pulmonary kinetics—with collaboration from a Physiology Department with a strong respiration group—contributed strongly to its successful construction.^(a)

We will close this review of the mechanisms and modeling activities at Rochester with a listing of some of the cogent reviews and pertinent discussion papers. These are in addition to the reviews provided at the termination of the MED days in the Uranium Monograph and reviews cited earlier in this chapter. They are in more or less chronological order:

1. *Retention of Submicron Aerosols in the Human Respiratory Tract* (Stannard and Morrow 1956)
2. *An Evaluation of Inhalation Hazards in the Nuclear Energy Industry* (Stannard 1959)
3. *Some Physical and Physiological Factors Controlling the Fate of Inhaled Substances. I. Deposition* (Morrow 1960); *II Retention* (Casarett 1960)
4. *Alveolar Reactivity Following Inhalation of Particles* (Casarett and Milley 1964)
5. *Evaluation of Inhalation Hazards Based upon the Respirable Dust Concept and the Philosophy and Application of Selective Sampling* (Morrow 1964)
6. *On the Role of Particle Size in the Dissolution of Lung Burdens* (Mercer 1967)
7. *Dose to Respiratory Tract After Continuous Inhalation of Radioactive Aerosols* (Kotrappa 1968)
8. *Models for the Study of Particle Retention and Elimination in the Lung* (Morrow 1970)
9. *Lymphatic Drainage of the Lung in Dust Clearance* (Morrow 1972)
10. *Observations Concerning Alveolar Dust Clearance* (Ferin 1972)
11. *The Deposition Model of the Task Group on Lung Dynamics: A Comparison with Recent Experimental Data* (Mercer 1975)
12. *Clearance Kinetics of Inhaled Particles* (Morrow 1977)

All but the first item involve review and analysis of research as the field developed with small additions of new research. Perusal of these should give a comprehensive and penetrating review of the field of this chapter, particularly since they quote work from all of the major laboratories in the United States and abroad. Any further discussion is impossible here, but the interested reader wishing an overview of the physiology and pharmacology separate from the details of behavior of elements of special interest to internal emitter toxicology will profit greatly by tracking them down.

D. Other Laboratories Contributing to Pulmonary Radiotoxicology

1. Overview

Several laboratories that were (and are) centers for research in the general fields of inhalation toxicology and aerosol science mounted significant efforts in pulmonary radiotoxicology. However, these were not on the all-consuming scale of

(a) Obviously, the years of work of the entire industrial dust fraternity played their role. This was not exclusively a Rochester show, but the Rochester talent and atmosphere played a key role.

those we have been discussing. Usually the work with the inhalation of radioactive materials in these laboratories involved fewer people and resources, was directed toward special problems or collaboration with other groups on special aspects of a larger problem. We will look briefly at the general nature of their contributions in this section. It will be obvious that some of the work is almost identical in concept to that carried on at what we have chosen to call "Centers," but on a smaller scale. Some is largely supportive to other groups. Some is mainly applied and directed toward engineering and control operations more than laboratory research. Because of the already ponderous amount of information we have had to review in this chapter, some of the contributions of these other laboratories will have to be presented largely by comparison of concept and results to the research we have already reviewed. Others will be discussed primarily in connection with the special problems that brought them into the field.

2. Harvard University

The Harvard School of Public Health has always had strong programs in the inhalation field, especially around the problems of ventilation, toxic gases, and air cleaning. Indeed, the periodic Harvard Air Cleaning Conferences are now an institution. We have noted that Philip Drinker, Professor of Industrial Hygiene at Harvard is coauthor with Hatch of "Industrial Dust" (1954). Leslie Silverman developed a myriad of methods in industrial hygiene. However, Harvard did not become deeply involved in pulmonary radiotoxicology. There were some significant contributions, primarily from one man.

Professor John B. Little got interested in the tumorigenicity of ^{210}Po . This was when work on the hot particle problem was rife and the promise of the Syrian hamster as a better test object in the rodent family than the rat was fading (see section V A). Little, Grossman, and O'Toole (1970) administered relatively small doses of ^{210}Po intratracheally to the hamster. The resulting crop of lung tumors and related pathology dispelled any doubts that the hamster could develop pulmonary cancer. With a calculated dose of 4,500 rad to whole lung, bronchogenic carcinomas appeared in 91% of the hamsters. They also induced carcinomas with the chemical carcinogen, benzo[a]pyrene (BaP). Later, McGandy et al. (1974) in Little's group demonstrated that the alpha-particle radiation plus BaP produced over twice the prevalence of lung tumors expected from either agent alone. In a later work, Little, McGandy, and Kennedy (1978) found that this apparent synergistic action, which was most characteristic when the BaP followed four months after the ^{210}Po , could be induced almost as well by instillations of 0.9% NaCl solution. Thus, we are again reminded that nature gives up her secrets with great reluctance. A seemingly innocuous stimulus may potentiate carcinogenesis—not a new finding, but new in this context. Little, Grossman, and O'Toole (1973) compared the effectiveness of ^{210}Po diluted in saline or after incubation with hematite particles ($0.75\text{-}\mu\text{m}$ mean diameter) as a carrier. The doses were multiple given over from seven to fifteen weeks. The polonium remained attached to the hematite particles, as demonstrated by autoradiography (also see Kennedy, Worcester, and Little 1977) and delivered a nonuniform dose to the lung, while the polonium in saline gave a much more uniform dose. It appeared that the hematite-bearing particles, while not carcinogenic in themselves, produced tumors somewhat earlier than the polonium in saline. On the other hand, when the dose and its distribution in space were manipulated, a lower but more uniformly distributed dose delivered to a larger volume of lung

tissue was more carcinogenic. This presents a dilemma that we will review further in the discussion of hot particles (section V A).

During this time, the question of radioactivity in tobacco smoke was coming to a head. Little's work contributed also to this, as we shall see in section V B.

Meanwhile, at the Harvard Medical School, Shields Warren, the dean of radiation pathologists, was interested in reactions of the lung to implanted radiation sources. It was Dr. Warren who sounded the alarm in the prewar years concerning radiation pneumonitis resulting from the ever-increasing energies and doses being used in x-ray therapy (Warren and Gates 1940). Warren and his long-term colleague Dr. Olive Gates implanted wires impregnated with ^{60}Co in the lungs of young adult rodents (Warren and Gates 1968). They compared eight strains of mice, Syrian Golden hamsters, guinea pigs, rats, and rabbits. Of 363 animals treated, about one-third developed bronchiogenic or epidermoid carcinoma. The rat, guinea pig, and rabbit also developed bone tumors. The mean total doses ranged from 8,500 r to 1,900,000 r.^(a) The lowest dose associated with cancer was 14,700 r. The rat seemed to be the most sensitive species. The histogenesis of the lung carcinomas was described in detail by Gates and Warren (1961). This paper contains also a useful table summarizing work to date on lung cancer production in rats.

This was part of a widespread interest in pulmonary cancer from implanted sources, as we will see presently.

3. Health and Safety Laboratory—Environmental Measurements Laboratory, New York City

We saw the involvement of this AEC-ERDA-DOE laboratory in radon work in chapter 3 and some of its general contributions to postwar research with internal emitters in chapter 8. The Laboratory devoted much of its effort to the development of methods and instrumentation, which were useful in a variety of programs both basic and applied. Apropos of inhalation problems, HASL was involved early in evaluation of inhalation hazards from uranium, thorium, beryllium, and other dusts in AEC-contractor installations and some independent companies (thorium). It took these duties over from Rochester at the end of the MED era. HASL has been a major contributor to evaluation of aerosol sampling methods and the development and perfection of air filter systems. When the fallout problems hit AEC, HASL became a major center for collecting, measuring, and evaluating fallout at both local and worldwide levels. It played a key role in health aspects of nearly every weapons test in both the Pacific and Nevada. (Details will be reserved for chapter 12.) HASL had much to do with making and evaluating environmental surveys, including the SNAP program, contamination around contractor plants, and the like. These included concern for inhalation hazards wherever they seemed important. Many of these will appear when we enter the environmental section of this book. In addition, in the middle years, HASL sponsored a number of training courses and symposia, mostly in applied fields.

HASL was involved directly in only a few laboratory experiments in the radioactive inhalation field. One of these, which came quite early (1950), was a study

(a) The expression of these doses in roentgens indicates that the work was done before the time of the full transition to rad and rem for all but external low-LET radiations.

of the elimination of inhaled radon (HASL-32). Another was the uranium dust clearance experiment in man carried out by Harris in 1960 and discussed in chapter 2.

Names to be associated with the contributions of HASL to inhalation toxicology are, among others, Merrill Eisenbud, John Harley, William Harris, Morton Lippmann, E. P. Hardy, Roy Albert, and A. J. Breslin.

Among the more general contributions are papers by Eisenbud on inhaled particles (Eisenbud 1952; Eisenbud and Quigley 1956) and the pertinent chapters in Eisenbud's book, *Environmental Radioactivity* (Eisenbud 1973). The many contributions of the Harleys on radon were seen in chapter 3, and those on fallout and the environment will be seen in chapters 12 and 13. An important review of natural radioactive materials in air appears in the chapter on inhaled radioactivity in NCRP report 45, which was prepared by a committee chaired by Dr. Harley (NCRP 1975b). Another example is the work on size-selective samplers described by Lippmann and Harris (1962).

Interest is still strong at the laboratory, now the Environmental Measurements Laboratory, in dust problems of industry and the environment, but it continues to involve primarily measurement, evaluation, and protection measures.

4. The Los Alamos Scientific Laboratory (LASL)

In the previous chapter, we saw that Los Alamos made major contributions to internal emitter toxicology in the postwar era. Here we will consider their work pertinent to pulmonary radiotoxicology.

There are some parallels to the activities we have just reviewed at HASL. There was a large and competent industrial hygiene group, which operated for many years under the eagle eye of Harry Schulte. They had to deal not only with uranium aerosols, but with plutonium aerosols. They could tolerate much less airborne activity than in the uranium operations. Much of their early postwar work, like their MED work, concerned evaluation of possible inhalation exposures to plutonium and the prevention of further exposure. By new construction, they gradually eliminated the worst trouble spots for airborne plutonium at the laboratory, but they had to be constantly vigilant and thoroughly professional in their attack. Some typical fairly early research tied to the practical industrial hygiene problems concerned particle size studies on plutonium and uranium (Hyatt, Moss, and Schulte 1959; Moss, Hyatt, and Schulte 1961; Andersen 1964); air sampling interpretation (Schulte 1967); and the ever-present bioassay program, which we dealt with briefly in chapters 7 and 8.^(a) Later contributions in the aerosol field centered upon the concept of "respirable dust," a special problem we will take up briefly in part V of this chapter, and ever better ways to measure, interpret, and protect against airborne contamination.

In the early postwar years, Los Alamos did very little laboratory experimentation in inhalation toxicology as distinct from the industrial hygiene operations. We saw in chapter 8 that the Los Alamos staff urged that inhalation work be done but eschewed taking it on themselves. Nevertheless, Los Alamos was a strong force in the field. Wright Langham and his group did many analyses of inhalation problems and were at the center of any national or international

(a) This program, of course, concerned excretion of material usually acquired by inhalation.

meeting where airborne hazards were under discussion. It appears that the Los Alamos input had much to do with focusing attention on inhalation hazards at the continental and Pacific weapons tests. Indeed, Wright Langham was considerably involved with the development of the so-called "safety shots" carried out at the Nevada Test Site and elsewhere to evaluate the dust and aerosol hazards from small-scale area contamination with plutonium (see chapter 14). It was Wright Langham and his Los Alamos colleagues who were called upon to evaluate the surface and airborne contamination problems at Palomares, Spain and Thule, Greenland (see Stannard 1973).

Because of its closeness to the weapons program, the Los Alamos Health Division staff was immediately and deeply involved in the problems of fallout. They were concerned with aerosol and meteorological aspects as they bore on hazard evaluation and did yeoman duty along with HASL in tracking and measuring fallout. Some of the experimental work described in chapter 8 was undoubtedly stimulated by the problems of fallout from the weapons testing program.

When J. W. (Jack) Healy came to Los Alamos from Hanford, he brought with him a keen interest in environmental contamination problems and the development of suitable information on the environmental transfer of radionuclides. Among his interests has been the problem of resuspension of deposited radionuclides, especially plutonium, by wind. He and others from Los Alamos have made many field observations of these phenomena. In addition, the laboratory built a small wind tunnel to promote experimental checks of the field observations (more in chapter 15).

Despite this considerable interest, the Los Alamos Laboratory was content for many years to let others do any needed inhalation experiments involving animals or man in the laboratory. This changed markedly when the hot particle problem stimulated greatly increased and cooperative efforts to solve it. As we saw earlier in the chapter, Hanford, Lovelace, and Los Alamos were tied into a coordinated effort on various aspects of the hot particle problem (see section V A). Los Alamos attacked the problem initially without having to set up inhalation studies by using intravenous injection of microspheres, but eventually some crosschecks were necessary in situ, and Los Alamos finally began to produce aerosols of radioactive materials for experimental use.

When Bob Thomas came up to Los Alamos from Lovelace he brought with him a keen interest in not only the hot particle problem, but the habit of doing inhalation toxicology experiments in the laboratory. Many of these are of general interest, and a few will be considered here. They are a continuation of his long-standing interest in particle transport, particularly the role of the tracheobronchial lymph nodes.

At the 1974 Hanford symposium on Radiation and the Lymphatic System, Thomas (1976) presented an analysis of the uptake kinetics of relatively insoluble particles by tracheobronchial lymph nodes. He developed models for uptake and loss, including a comparison of first-order and power-function kinetics. He concluded that we need still more work to choose a "best" model.

Toward the end of the decade of the seventies, Thomas and colleagues proved that Pu-ZrO₂ particles could indeed produce respiratory-tract tumors in the Syrian Golden hamster after many years of puzzlingly negative results (see Thomas and Smith 1979a; Smith, Thomas, and Anderson 1980; Thomas, Smith, and Anderson 1980). Thomas also prepared a book on the Syrian Golden hamster as a useful laboratory animal.

Also during the decade of the 1970s, the Los Alamos group moved strongly away from their earlier interests and emphasized molecular and cellular radiobiology. Some of this interest spilled over into the inhalation work. An example is the studies by A. Stroud on chromosome aberrations. In a series of reports in the annual reviews and in published work, Stroud (1977) studied lung cells from hamsters that had small lung burdens of ^{238}Pu in plutonium-zirconium microspheres (initial burden, 130 nCi). The cultured cells, still in the excised lung, showed an 18% to 26% increase in chromosome aberrations (abnormal metaphases) and considerable depression of growth rate and mitosis. Autoradiography demonstrated many star clusters of alpha tracks. Of special interest is the fact that these changes occurred under conditions where no histological effects were seen in the lung sections, and very few lung tumors occurred. (See work by Richmond and others in the section on the hot particle problem.) Apparently, the damaged cells did not survive in general, although a few with minor damage might be transformed to precancerous forms.

Finally we should remember that the long-term follow-up of the Los Alamos plutonium workers, which we will review in chapter 16, is basically an inhalation toxicology problem, since the route of exposure was primarily by inhalation.

5. New York University, Institute of Industrial Medicine (Later Environmental Medicine)

This organization, put together just after World War II, has been an important factor in American aerosol science, toxicology, epidemiology, oncology, and environmental science. Under the decades-long leadership of Dr. Norton Nelson,^(a) a pillar in the field of occupational medicine and later of environmental medicine, the institute has grown and prospered.^(b) It has centered on chemical toxicology, chemical carcinogenesis, respiratory function, and respiratory disease with occasional forays into and a few long-term programs in the radiation field. They pioneered some important work in pulmonary radiotoxicology.

The institute began its work in the medical school buildings on First Avenue in New York City. During 1963–1964, the Anthony J. Lanza Research Laboratory for research in environmental medicine was constructed at Sterling Forest, near Tuxedo, New York, about fifty miles from the city. Most of the radioactivity and animal programs were moved or developed there. A picture of a part of this facility adorns the inside cover of each annual report from NYU and is reproduced here as figure 9.36. We show it to emphasize the arboreal surroundings possible even at NYU. Still later, the laboratory of Aerosol Technology occupied additional space in former Bellevue Hospital buildings in the city.

The institute engaged early, along with others, in studies of the clearance of radioactive dust from the human (Albert and Arnett 1955) built initially around problems of radon and thoron. They used kaolin dust mixed with thoron gas and measured the behavior of the dust by detection of the ThB with an external crystal counter. They also used metallic iron powder activated by neutrons in a reactor. They measured effective half-life, found that bronchial clearance had

(a) Dr. Arthur Upton, formerly of Oak Ridge National Laboratory and recently director of the National Cancer Institute succeeded Dr. Nelson in 1981.

(b) The Institute became the Institute of Environmental Medicine about the time fallout became a major concern.

FIGURE 9.36. The Anthony J. Lanza Research Laboratories of New York University for research in environmental medicine at University Valley in Sterling Forest, New York.

two phases, and reconfirmed the finding that larger particle sizes were removed more rapidly than smaller. (Note the use of man in this and many other NYU experiments.)

This was followed by a long series of experiments on deposition and clearance (Albert et al. 1967a,b; Lippmann and Albert 1969; Lippmann 1970a). Early on, the work was done primarily to measure the kinetics of transfer of the particular radionuclide concerned. However, the convenience of using particles tagged with radioisotopes gradually shifted the emphasis to use of the radioactive aerosols as tools for measuring pulmonary function after exposure to various toxicants or during the development of respiratory disease. The convenience was enhanced by an NYU-pioneered technique of producing monodisperse insoluble aerosols that could be doubly labeled, one with ^{198}Au , the other with $^{99\text{m}}\text{Tc}$, in different size ranges (Albert and Lippmann 1968). They made over forty human inhalation tests in one year and a series of experiments with miniature donkeys.^(a) They characterized the phases of clearance and demonstrated the abnormal patterns in cigarette smokers and after pulmonary irritants. Each year saw further diversification of this methodology. In 1974, their use for diagnostic evaluations was described; in 1975 came a possible use for screening tests, etc. They had become a tool for nuclear medicine. Good bibliographies and expositions of this work occur in the annual report series from the Institute of Environmental Medicine each year.

(a) The inhalation equipment for donkeys is described by Lippmann (1970b).

Very early, the NYU group implanted radioactive sources in the lungs of rats and were among the first^(a) to demonstrate squamous metaplasia of the bronchial epithelium and squamous cell carcinoma of bronchial origin from beta radiation of the ^{106}Ru - ^{106}Rh couplet. Doses ranged from 7×10^{-3} to $14 \mu\text{Ci}$. Cancers appeared as early as eight months at doses of about 2×10^5 rad and metaplasia within six days and a dose of only 70 rad (Kuschnier et al. 1957). This report contains numerous clear examples of the histological changes seen. The work was published in 1958 (Kuschnier et al. 1958), and the dosimetry was published by Altshuler (1958). The application to airborne radioactive substances was reviewed by Nelson (1961).

Sidney Laskin, who had come to NYU from Rochester, used the implantation technique for many chemical carcinogens as well as for radioactive sources. A summary of the latter was given at the Hanford symposium in 1964 (Laskin et al. 1964) and dose-response information in 1963 (Laskin et al. 1963). They also applied their considerable expertise in aerosol science to the development of true inhalation experiments. They concentrated primarily on inhalation of chemical carcinogens, but never lost touch with the radionuclide field.

As part of work concerning radon, radon daughters, and uranium miner problems that we saw in chapter 3, Pasternak and Harley became involved in very generalized dosimetry work with alpha emitters. For reasons that are not clear from the brief expositions in the reports, they postulate the relative toxicity of thorium daughters as twenty times that of equal airborne concentrations of radon daughters, and the relative toxicity of ^{239}Pu particles as five times that of radon daughters. For the plutonium work, they tagged iron oxide particles with ^{239}Pu and measured absorption of the alpha particles in thin "tissue-like" films. This dosimetry work has concentrated on cell dose. It is continuing (see for example Cohen, Eisenbud, and Harley 1980). However, it is more a part of the radon/uranium-miner/uranium-mill problems and the material we considered in chapter 8 than the special problems of this chapter.

The NYU group was deeply involved in air pollution problems. One study that has generated much interest concerned the radioactivity in atmospheric effluents from fossil fuel power plants. Eisenbud and Petrow (1964) concluded from measurements at several power plants that a 1,000-MW coal-burning plant would discharge to the atmosphere from 28 mCi to about 1 Ci/yr of ^{226}Ra and ^{228}Ra . This is, of course, from the natural radioactive materials in the coal. A similar-sized oil-burning plant would discharge much less, about 0.5 mCi/yr. Eisenbud concludes that these quantities exceed the normal releases of fission products from comparably sized nuclear power plants.^(b) In addition, of course, the fossil fuel plant releases fly ash, SO_2 , etc.

Other facets of NYU's rather extensive program on radionuclides either do not concern inhalation problems, have already been discussed in chapters 3 and 8 (NYU 1974), or concern environmental and accidental intakes by humans, which we will review subsequently. Obviously, the contributions have been major but are spread broadly among several fields.

(a) The NYU and Pittsburgh work (see below) seems to have been done over essentially the same time period. (See section D 7.)

(b) This concerns only normal operations in both cases, not emergency releases.

6. Oak Ridge National Laboratory, Biology and Health Physics Divisions

a. Health Physics Division

During and after the war years, operational problems at the Y-12 plant at Oak Ridge often raised questions about determination of lung burdens. In some instances, specific inhalation research was requested (e.g., memo from Sapirie to Dunham 1966), but it was not intended that the research be done at Oak Ridge National Laboratory (ORNL). It was a matter of pushing the AEC to see that some of the local problems, such as high-fired oxide aerosols, were attacked by one of the inhalation laboratories. The laboratories were quite responsive. However, the Health Physics Division found it necessary to mount a few inhalation experiments of its own with uranium isotopes. These were in response to practical problems of occupational exposure in the plant, including the finding of workers with significant levels of uranium isotopes in urine samples.

Muir et al. (1959) and Fish (1961) report on inhalation of uranium aerosols by mouse, rat, dog, and man. Long-term retention of U_3O_8 was indicated in lungs and pulmonary lymph nodes, but no toxic effects were noted. The primary purpose—correlation of lung burden with urinary excretion—was met in part. The abstract of this paper conveys the substance of the results:

Six cases of accidental inhalation of uranium compounds have been studied to compare various methods of estimating body burden. One accident, involving U_3O_8 , was re-enacted and an estimate of potential lung burden was derived from air sampling data; this, along with estimates based upon blood analysis and urinalysis, compares with in vivo gamma counting results with ± 50 per cent. Two cases of uranyl nitrate inhalation were analyzed by comparing the individual uranium excretion rates with those of twelve humans given known intravenous injections, and also by collecting all of the urine for long periods of time: the estimates agree to within a factor of 2. Data obtained from these accidental exposures, along with a field study correlating air contamination parameters and uranium excretion levels for a variety of industrial jobs, have been used to fashion a tentative empirical model relating body burden to air contamination and to excretion.

Dogs exposed to a single inhalation of uranium fumes (U_3O_8) retain approximately 25 percent of the inhaled material. About half of the retained lung burden is eliminated rapidly with a biological half-life of 4-1/2 days while the remainder is cleared at a rate of half every 100 days. About 0.01 percent of the portion that is eliminated via the gastro-intestinal tract is absorbed into the bloodstream. The concentration of uranium in the tracheo-bronchial lymph nodes increases while the amount in the lungs decreases so that after about 4 months the uranium concentration in the lymph tissue exceeds that in the lung.

In vitro studies of the solubilities of U_3O_8 and uranyl nitrate in an ultra-filtrate of blood as a function of particle size have been initiated. Animal inhalation projects, now under way, are designed to simulate with mice, rats and dogs the actual exposures presented to the human subjects. Correlation of the industrial exposure data with the laboratory studies tends to support the empirical model.

(Fish 1961)

This work shows in detail the in-plant layouts for the human exposures on a case-by-case basis along with estimates of lung burden from urinalysis, blood samples, air samples, and in-vivo counting, also the change in lung burden with time—all of interest for correlation with the animal data and experience after intravenous injection in humans.

Of similar interest is a report on four cases of employees showing unusually long retention of uranium dust (West and Scott 1969). Despite diligent efforts, they could not establish completely the reasons for the unusual retention times

in these cases. Animal work at Hanford using the same material did not confirm this long retention time.

b. Biology Division

In the mid-1960s, the Biology Division entered upon a cooperative program in carcinogenesis with the National Cancer Institute. It was known as the Carcinogenesis Program of the Biology Division. This did not use radionuclides per se, so a detailed review is beyond our scope. In principle, the program was oriented toward smog problems and chemical carcinogenesis. It called for use of specific-pathogen-free mice, some of which received 100 R whole-body x-radiation and/or infection with influenza virus. They were then placed in inhalation chambers and exposed to either ozonized gasoline or an insoluble chromium oxide dust. A typical result of this program is seen in a paper by Nettesheim and colleagues given at the Oak Ridge symposium in October 1969 (Nettesheim et al. 1970). There were sex differences in effectiveness. For example, irradiation raised the incidence of lung tumors in female mice but not in males. Tumors were largely adenomas and adenocarcinomas. The combination of treatments had little in the way of additive or potentiating effects. At this same meeting, Kastenbaum urged more application of factorial experiments to the inhalation field (Kastenbaum and Mitchell 1970).

7. University of Pittsburgh Graduate School of Public Health and University of Cincinnati Kettering Laboratory

Under the influence of Theodore Hatch, long-time professor of industrial health engineering, and his colleagues, the University of Pittsburgh School of Public Health and the Industrial Hygiene Foundation of the Mellon Institute have a many-decade reputation as centers for inhalation toxicology. We were introduced to the classic text by Drinker (Harvard) and Hatch at the beginning of this chapter and noted that the first edition was published in 1936. Soon after the end of the war, Hatch's laboratory published a definitive review of particle-size effects on retention in the human lung (Brown et al. 1950) based in part on work done for the Chemical Corps, U.S. Army.^(a)

In the early 1950s, the laboratory acquired Herman Cember as a graduate student (M.S. 1952, Ph.D. 1960). Under the supervision of Ted Hatch, he became something close to a one-man show in pulmonary radiotoxicology. He studied pulmonary retention and clearance with small particles of radioisotopes; he implanted beads of ^{90}Sr in the lungs of rats; he produced bronchogenic carcinoma with ^{144}Ce fluoride insufflation; and he attacked the hot particle problem long before it became a problem. In short, he demonstrated or confirmed many of the phenomena that were more laboriously developed by the true inhalation experiments elsewhere.

It started with work on the pulmonary penetration of particles administered by intratracheal insufflation (Cember et al. 1954).^(b) They used radioactive

(a) It appears that every laboratory had its share of reviews on deposition, retention, and clearance of dust. These are not unduly repetitive. Many introduced their own experimental approaches. There are a few conflicts, but, on the whole, each adds something to the accumulated wisdom on the subject.

(b) Yes, Cember did have collaborators, but the arrangement was quite different from the large groups we have been considering heretofore in this chapter.

barium sulfate^(a) and measured particle retention and distribution by autoradiography. They concluded that about 40% of the amount intubated reached the deep respiratory tract. They did not see much pulmonary damage and were puzzled that they saw much less than Lisco and Finkel (1949) had found with ^{144}Ce oxide. A possible explanation was more general tissue distribution of the cerium oxide, which was a fume. In a later experiment with multiple injections and a longer observation period, they found extensive pulmonary damage, squamous metaplasia, and squamous cell carcinomas, even from a beta emitter of such low energy as ^{35}S (Cember and Watson 1958a).

Like many other investigators entering the pulmonary radiotoxicology field, the Pittsburgh group was surprised by the relatively rapid clearance from the lung of a substance like barium sulfate considered to be extremely insoluble *in vitro*. They turned to thallium-activated clay particles using the same montmorillonite clay adapted later by the Lovelace group (Cember, Watson, and Grucci 1957). They got longer retention and, of course, very nonuniform distribution of dose, but no biologic effects in rats over a nine-month period. The doses were not high.

Intrigued by the results of Lisco and Finkel (1949) with ^{144}Ce and pessimistic about lung cancer being caused by radioactivity because of the relative dearth of reports of lung tumor formation in either animals or man in the few studies reported through the early 1950s,^(b) Cember and colleagues gave $^{144}\text{CeF}_3$ by intratracheal insufflation at doses of 0, 5, 15, 25, and 50 μCi per rat. Bronchogenic carcinoma was observed in each group with frequencies of 1/27, 1/23, 7/28, and 4/15, respectively. The minimum tumorigenic dose was calculated as 2,400 rad.

The work with ^{90}Sr beads paralleled in concept the experiments discussed at Harvard and NYU above. The rationale came out of findings that x-ray doses to the lung were much more effective than point sources (e.g., ^{35}S) giving the same dose (Cember et al. 1954, 1955). Using a solid bead permitted more precise definition of dose and its distribution (so long as the bead remained intact) and was regarded as more uniform than the radioactive particulate source. Twenty-three rats received one radioactive bead each, twenty rats received nonradioactive beads (stable strontium-glass), and there were two types of controls. The survival patterns up to 550 days were not different between the groups receiving the radioactive beads and those receiving the nonradioactive beads. Both groups suffered from the trauma of the lung puncture. However, the group with the implanted ^{90}Sr beads produced a number of primary malignant tumors, all but one associated with the bead. There were four squamous cell carcinomas. The dose rates were from 160 to 660 rad/day and total time of the exposures hundreds of days. Hence, the total radiation dose was enormous and the effectiveness per rad much lower than the uniform x-ray dose. The experiment did prove at a time when there was not very much information that a source of radioactivity in the lung could produce lung cancer (Cember and Watson 1958b).

We have not quoted all of the pulmonary radiotoxicology work done at Pittsburgh, but we have a fair sample. Cember avoided the complexities of producing aerosols of radioactive materials and was able to cover quickly ground that the later very large experiments covered more deliberately and in greater detail (for review see Cember 1964a).

(a) The tag was ^{35}S . Clearance was measured also with mercury sulfide tagged with ^{203}Hg .

(b) How things have changed!

In 1960, Cember received his Ph.D. and moved to the famous Kettering Laboratory at the University of Cincinnati. He continued his work in pulmonary toxicology there. In 1963, he took part in the IAEA symposium on mining and milling of nuclear materials with a review on pulmonary cancer (Cember 1964b). At the Hanford symposium on Inhaled Particles and Gases he presented new results (1964a) on intratracheal injection of ^{144}Ce in rats at doses from 0.5 to 50 μCi .^(a) He found lung cancer at every level and established a dose-response relationship that was concave upward or what Dr. Cember called "the lower half of an ogive-shaped dose-response curve." The lowest dose was at about 700 rad. An average cumulative incidence frequency of about 2% was associated with this dose, but the confidence band went from below the abscissa to about 8%.

Later, Cember took on very broad teaching responsibilities, moved to Northwestern University, wrote a broadly based textbook of health physics, and went on to other things. Plaudits are due him for the number of basic areas in pulmonary radiotoxicology he was able to cover, many in a pioneering manner.

8. Wayne State University

Arthur Vorwald, a pathologist with many years of experience in pulmonary pathology at institutions like the Trudeau Sanitarium at Saranac Lake, New York, spent the war years in the U.S. Navy. There he became interested in various problems of toxic gases and high-altitude physiology. Soon after the war, he organized a center for the study of air pollution problems at the Wayne State University Medical School in Detroit. They had a variety of experiments, including one in which the air from an arterial street beside the school was piped into animal exposure chambers.

A part of the program was a study of the inhalation toxicology of the rare earth elements, a somewhat neglected area. Harry Berke, who was a part of the original Alpha Laboratory group at Rochester, joined the staff to carry on work with some of the radioactive isotopes of the rare earths, as did Donald Willard who migrated from Hanford. The basic plan was, as I recall, to compare various mixtures of stable and radioactive isotopes of rare earth elements to check on possible chemical toxicity and/or carrier effects; also to compare beta-particle effects with those of x-irradiation. We can give only an example or two of the results from this laboratory.

Berke, Wilson, and Berke (1968) and Berke and Deitch (1970) used $^{152-154}\text{Eu}$ in rats. This radioisotope has a mixture of beta and gamma emissions. They gave repetitive exposures, seven hours per day, five days per week, for twenty-four weeks. Maximum concentrations reached on this regimen were about $18 \times 10^{-3} \mu\text{Ci/g}$ whole body or $150 \times 10^{-3} \mu\text{Ci/g}$ lung. Cumulative radiation doses were about 8×10^3 rad whole body and 60×10^3 to lung.

In the 1969 paper, the authors describe changes in the ratio of large to small lymphocytes. It increased progressively in exponential relationship to cumulative exposure. Since the results paralleled those of repetitive x-irradiation, the Wayne State group felt that this ratio might be useful in internal emitter work for measuring dose equivalence.

(a) This experiment and the one reported from Pittsburgh seem almost identical. Perhaps it was an extension or a recasting of those results.

The 1970 paper concerns carcinogenesis. The rats developed severe inflammatory changes in the lungs, but no neoplasias were seen. This was just before the Lovelace work on beta-gamma emitters had reached open literature publication. The authors wondered if beta particles might not have a low tumorigenic potential. In retrospect, it appears that the doses were very large—perhaps so large that the lung pathology overwhelmed the development of cancer. Yet, in later work, cancer has appeared at beta-gamma doses in the same range or even higher. No ready explanation comes to mind.

Later the laboratory published studies of mucociliary transport rate using roentgenography and a radiopaque medium placed in the trachea of a lightly anesthetized rat (Berke and Roslinski 1971), as well as work in other areas of toxicology.

9. Other U.S. Work

The inhalation problems were sufficiently pressing and sufficiently universal that occasional experiments were done in laboratories not engaged in the mainstream or even the sidestream efforts.

Argonne National Laboratory got involved in some pulmonary studies through accidental exposures to radium (of course radium was a mainstream effort at Argonne). Marinelli and Gustafson (1952) and Marinelli et al. (1953, 1958) measured the transport of radium sulfate from the lung as well as its excretion. They found sharp localization of the deposits in lung and individual differences in elimination. The average half-life in the thorax was 120 days in the first year.

Miller and Corcoran (1958) applied their newly developed whole-body counter to estimate very long-term retention (2,300 days) of radium, and Marinelli et al. (1958) obtained information on excretion as well as retention over long periods after an accidental inhalation.

Much later, Rundo and Sedlet (1973) studied retention and elimination of ^{249}Bk - ^{249}Cf following an acute accidental inhalation.

Paul Ziemer's laboratory at Purdue suddenly did some work with europium (Johnson and Ziemer 1971). Results were of interest in that, among other things, whole-body retention could be described equally well by two mathematical models, a dual-term exponential or a power function of time. This work was tied into a general interest at the laboratory in the biological effects of the rare earths.

There are undoubtedly isolated pieces of U.S. work that have been missed. Nevertheless, the quantity and quality of material we have now reviewed in this chapter and in chapters 2 and 3 should be enough to convince anyone that the United States mounted more than adequate programs to deal experimentally with the problems of inhaled radioactive materials.

10. Work Abroad

Space limitations and the scope for this book permit only the briefest consideration of work abroad, except where the early history took place largely in other countries. France and the Soviet Union have conducted the most extensive experimental programs in pulmonary radiotoxicology. Despite outstanding work in aerosol science and major contributions to internal emitter toxicology in Great Britain, the two did not join forces very often in experimental work. In pulmonary radiotoxicology, the United Kingdom has acted more as a coordinator and reviewer of the problems and their interpretation than a developer of

new information, with some notable exceptions. Japan began inhalation studies on plutonium and fission products when their reactor program began to develop. There is an alpha emitter facility at the National Institute of Radiological Sciences in Chiba City patterned in part after Rochester's Alpha Laboratory, and Pacific Northwest Laboratory. West Germany has produced several key studies (see chapter 3). Workers in Finland and Eastern Europe have exhibited considerable interest and done significant but not numerous experimental studies.

Since space prohibits even a listing of key papers, it is suggested that the literature be pursued by reference to one or more of the reviews cited in this chapter, as well as the specific citations concerning radon and uranium mining problems in chapter 3. Especially helpful would be the reviews by Bair and colleagues in the *Handbook of Experimental Pharmacology*, Vol. 36 (Bair et al. 1973); the several publications of the IAEA, especially *Radiological Health and Safety in Mining and Milling of Nuclear Materials*; ICRP Publication 31 (1980); the several translations of *Doklady Biophysics* and the Moskalev Monograph (1966) translated by the U.S. AEC; the series of books from the USSR on specific elements edited by Letavet and Kurlyandskaya (1962–1970) and translated by Dolphin (Pergamon Press); the Hanford symposia, especially the one on Inhaled Particles and Gases in 1964; and the publications of the United Nations Scientific Committee on Effects of Atomic Radiation (UNSCEAR).^(a)

Individuals and institutions frequently cited, and thus ones to be watched for especially, are:

Austria: Pohl and Pohl-Rüling
 Belgium: Dautrebande
 Finland: Miettinen
 France: Commissariat à l'Energie Atomique, Fontenay-aux-Roses—Chameaud, Perraud, Lafuma, Masse, Metivier, Morin, Nénot, Nolibé
 Japan: National Institute of Radiological Sciences—Suzuki, Matsuoka.
 Great Britain: Medical Research Council, National Radiological Protection Board, United Kingdom Atomic Energy Committee, University of Newcastle upon Tyne—Clarke, Dolphin, Eve, Mayneord, Smith, Stewart, Thorne, Vennart, James, Stradling
 Federal Republic of Germany: Feinendegen, Hug, Jacobi, Schmidke
 Yugoslavia: Djurić
 Soviet Union: Buldakov, Burykina, Lyupchanskii, Kurlyandskaya, Lemberg, Moskalev, Nifatov
 Sweden: Walinder

V. Special Problems

Most of the work in pulmonary radiotoxicology, both in the MED days and in the postwar era, was based on operational problems, either encountered or anticipated. There were a few special problems that attracted the attention of every laboratory in the field and others that were best attacked by interlaboratory groups brought into focus by administration. Some of these stimulated significant new research efforts, particularly in the early postwar era. Others required primarily application of knowledge already gained. They are best discussed as entities and are brought together in this section.

(a) Remember that work primarily on radon and uranium mining was cited in chapter 3.

A. The Hot Particle Problem

Honors for being the most diversionary, most divisive, and most expensive go to the so-called "hot particle" problem. Simply stated, this revolves around the question as to whether or not a small discrete source of radiation in the lung is uniquely carcinogenic. This is nothing new. It had been fully recognized in the early work with both lung and bone, but was presented in a sensational manner.

This is part of a dilemma that has for many decades dogged the footsteps of both those devising regulatory standards and those interested in basic problems of internal dosimetry. It has been known ever since the first autoradiographs showed that deposited radionuclides either entered the body in aggregated form or became aggregated *in vivo*. Especially serious attention was devoted to this phenomenon by those working with bone and bone-seeking elements. We have seen numerous instances of the phenomena themselves in earlier chapters and in earlier parts of this chapter. Investigators in the inhalation field have mused for years on the question of the relative effectiveness of the same total dose to lung received in different patterns. Hot particles were noted at Hanford and at Oak Ridge in the 1940s (Morgan 1948). They called them "specks" then.

However, the hot particle problem we are discussing arose suddenly in 1974. An organization known as the Natural Resources Defense Council (NRDC) produced an analysis that concluded, partly by logic, partly by assumption, that hot particles (i.e., radioactively "hot") were uniquely carcinogenic and that the current maximum permissible lung content of ^{239}Pu was 115,000 times too high^(a) (Tamplin and Cochran 1974). This was followed by an official petition to both AEC and the U.S. Environmental Protection Agency (EPA) for a 115,000-fold reduction in radiation standards applicable to plutonium and other actinides.

The back-up material for the petition made use of many of the experimental results we have already reviewed. It also brought in some evidence from the external radiation field. The story has been told very well in many places and many times. Probably the most complete factually are the reviews by Bair, Richmond, and Wachholz (1974); Richmond (1975, 1976); Healy, Richmond, and Anderson (1974); NCRP (1975a); NAS-NRC (1976); and Part G of ICRP Publication 31 (ICRP 1980). Nevertheless, we must review the story briefly because of its role in pulmonary radiotoxicology and in order to appreciate the new research and analyses of old research stimulated by this event.

The impact of the NRDC report and petition was enormous. The low-level radiation controversy was in a phase of logarithmic growth. The LMFBR program, which could produce potentially very large quantities of plutonium, was being pushed by AEC. Environmental Impact Statements were being written for everything, and the one for the LMFBR received considerable attention with numerous hearings. There was much opposition to manufacturing more plutonium. The Congress and executive branches of the U.S. government jumped in vigorously. The public was upset and astonished to hear that the standards whose credibility was already being eroded might be off by such an enormous factor. Blue-ribbon committees were appointed both within and outside of government, on both sides of the Atlantic, to examine the situation and make recommendations. The AEC encouraged its laboratories to undertake some

(a) Note that they were so sure of themselves they did not round the number off to 100,000 or simply 10^5 .

critical experiments that might fill in some of the important gaps in our knowledge. Investigators who felt their results had been misinterpreted or misused produced statements and/or went back to do more experiments.

A brief review of the original premises and what happened later follows.

1. The Proposition

The hot particle proposition as enunciated by NRDC contains, among others, the following basic premises and ideas:

- a. It is well known that plutonium and other actinides, particularly in their insoluble forms, deposit and remain in lungs in the form of particles. These particles disappear very slowly.
- b. The dose rate around such particles can be extremely high and presents a unique hazard for the production of lung cancer.
- c. Plutonium is one of the most potent carcinogens known.
- d. The assumption of average dose to lung as the pertinent one for cancer production is incorrect.
- e. The work of Dr. Roy Albert^(a) at NYU using rat skin exposed to electron and later alpha-particle radiation, showed that sensitive target cells resided in hair follicles about 0.3 mm below the surface of rat skin. Radiation focused into the hair follicles was very effective in producing skin cancer. In other words, there were small foci of considerably elevated sensitivity. The NRDC used this work to back its argument.
- f. This and correlations from it were termed the "Geesaman hypothesis," which stated that a sufficiently high dose to a critical architectural unit carried chances of cancer induction of 10^{-3} to 10^{-4} *per unit*. It had appeared in a report from the University of California Radiation Laboratory some years before the NRDC report was written (Geesaman 1968).
- g. Work of Bair et al. indicated the high potential for lung cancer in dogs receiving plutonium. It was postulated that this applied also to humans. Furthermore, a summary by Sanders, Thompson, and Bair (1970) concluded that nonuniform radiation (a point source) was more carcinogenic than a uniform radiation dose from an external source. They also presented a model showing increased estimated incidence of lung cancer with increasing particle size.^(b)
- h. A minute lesion in the hand of a plutonium worker caused by an imbedded plutonium particle became cancerous. (The particle had been removed by surgery soon after the incident.)
- i. A freight handler who handled a crate containing a leaking carboy of a plutonium solution received contamination of the hands, which led subsequently, according to Gofman and Tamplin, to soft tissue sarcoma on the left palm, which produced his death.
- j. The work of Laskin on imbedded sources in the lung had demonstrated production of lung cancer at doses as low as 1,400 rad.

(a) For references, see, for example, Bair, Richmond, and Wachholz (1974).

(b) This review was based upon early data, most of which involved intratracheal administration or the implantation of radioactive particles, beads, or similar sources. See subsequent and earlier sections for results of inhalation exposures.

- k. Exposures of humans to hot particles were already occurring at Rocky Flats, had occurred at Los Alamos, and elsewhere.

Out of all of this and more, Tamplin and Cochran decided that certain criteria of activity and dose rate were required to initiate the hot particle reaction. They defined a hot particle as one that presented a risk of cancer induction between $1/1,000$ and $1/10,000$. They chose to use a $1/2,000$ risk per particle. Meeting this criterion would be ^{239}Pu particles containing 0.07 pCi or more of activity. Such a particle would deliver $1,000$ rem per year or more, the "threshold" dose rate. The limit for occupational exposure should be 0.14 pCi or two of the standard hot particles.

It should be noted that the hypothesis allows for plutonium being in a form other than hot particles and implies a threshold-type response.

2. Some Immediate Responses

There were some immediate rebuttals and comments on these postulates, as follows:

- a. Albert was quick to point out that for a tumor to occur he had to include the whole hair follicle, a much larger area than that around a hot particle as defined. In fact, using focal alpha radiation he found it impossible to induce skin cancer no matter what the dose if smaller volumes were irradiated. Also, Albert pointed out that tissue damage and carcinogenicity are by no means parallel. (The chronic irritation theory of carcinogenesis, enunciated by Virchow in 1863, is no longer tenable.) There is little relation in a general sense between degree of tissue damage and cancer induction. The rat skin experiments actually showed protection for low-LET radiation when a sieve pattern replaced irradiation of the full area. Finally, the phenomenon could not be produced in other species.
- b. The enormous doses around hot particles would be more likely to kill surrounding cells than to transform them to precancerous cells.
- c. Inhaled material is constantly moving around in the lung. Only when fixed in scar tissue would a hot particle remain as a fixed source.
- d. Phagocytosis and other processes result in aggregates of material no matter in what form it enters. The entry form governs only the initial behavior.
- e. Bair and colleagues pointed out that the differences they had found between different forms of plutonium and different particle sizes were far smaller than the postulates of the hot particle hypothesis required and applied more to one experiment than to another, i.e., it was not established yet as a universal phenomenon despite the model proposed in 1970.
- f. The pathologists termed the lesion in the hand of the plutonium worker only precancerous and not clearly related to the previously imbedded particle. The cancer of the freight handler was not clearly due to the small radiation exposure incurred.
- g. Alpha-particle irradiation does not usually exhibit a threshold-type response.
- h. The hypothesis as stated has many problems of logic. An example is that the risk from a particle of approximately 0.1 pCi of plutonium would be decreased by a factor of over $100,000$ if the particle were to break into two equal halves.
- i. he exposed plutonium workers at Rocky Flats and Los Alamos already had many more hot particles than two. In fact, nearly everyone does. Many

cases of lung cancer should have appeared over the long periods (over thirty years now in some cases) if the risk were 1/2,000 per particle. To date, not a single case of lung cancer or other cancer clearly associated with radiation has appeared in these workers, despite diligent examinations and follow-ups: (There are those who say these analyses are faulty, e.g., Martell.)

Some of these ideas appeared in hearings on the LMFBR held by the EPA. Some appeared in reports of expert committees convened to examine the problems. Among these are reports of the U.S. National Academy of Sciences—National Research Council (NAS-NRC 1976), U.S. National Council on Radiation Protection and Measurements (NCRP 1975a), The Biophysical Society (1974), and the U.K. National Radiological Protection Board (Dolphin 1974). Specific reviews came from individual laboratories also (e.g., Healy, Richmond, and Anderson 1974; Richmond 1975, 1976), and a full review was done by Bair, Richmond, and Wachholz (1974) as an AEC report.

The NRDC issued critiques of some of these documents. These appeared as NRDC reports, sometimes as part of the hearings process on the LMFBR.

The many reports examining the NRDC report and proposal were uniformly negative in essence. Some objected to the whole idea, others felt a service had been rendered by highlighting the problem, but that the petition had gone much too far. Many called for more research. All agreed we did not have good evidence that particulate sources were more carcinogenic than discrete sources.^(a)

Enough about the polemic. It is the research associated with or pertinent to this polemic that is our primary interest here. The balance of our discussion will review work done wholly or in part in response to these problems. Much of it was clearly in progress before 1974, but it was accelerated and expanded by the hot particle controversy.

3. Contemporary Experimental Work Pertinent to the Hot Particle Proposal

a. Experimental Approach

The work most obviously directed at the hot particle problem took place at Los Alamos. They wanted to check on the effects of fixed sources but to avoid the trauma associated with implanting beads and wires. Richmond, Langham, and Stone (1970) investigated the effects of $^{238}\text{PuO}_2$ particles lodged in lung vasculature after intravenous injection. There was a small microlesion around the particle with complete degeneration of the cells close to the particle, but no cancer-like changes.

The Los Alamos group then turned to the use of microspheres. These inert particles, developed by the Nuclear Products for Medicine branch of the 3M Company, were already in use for clinical and therapeutic applications in nuclear medicine. They were available in a variety of controlled sizes and could

(a) Several of the analyses did review the few experiments already done that addressed specifically and in a controlled manner the question of discrete versus diffuse radiation sources. Many of these were, like Albert's work, concerned with effects in skin (e.g., plaques of P-32). The evidence indicated that the more uniform source was the more damaging in general. (The pertinent experiments are cited in the references already given.)

be treated to carry varying amounts of radioactivity. By selecting a size that would be caught in the smaller blood vessels of the lung, a static source could be produced by intravenous injection of such microspheres. The animal chosen was the Syrian hamster for the reasons given in section IV. The nominal levels, specific activity, equivalent diameter of pure $^{238}\text{PuO}_2$, and the PuO_2 weight fraction in their early experiments are given by Richmond, Langham, and Stone (1970, table 7). There were in toto over 150 hot particle experiments carried out at Los Alamos.^(a)

As the experiments progressed, the investigators were surprised at the lack of biological effects. Animals taken by serial sacrifice showed minor changes around the source, and, as the levels were increased, some radiation pneumonitis. Lung tumors or even metaplasia were of conspicuously low incidence. In approximately 1,150 hamsters living their full life spans with about six million microspheres with specific activities above 0.07 pCi each, only three primary lung tumors occurred. The associated tumor risk was calculated to be about 10^{-7} per particle instead of the 10^{-3} of the Geesaman hypothesis. Is the hamster unusually resistant to lung tumor formation? We have already seen that Little at Harvard easily produced lung tumors in the same species and strain of animals with instilled ^{210}Po . Also, chemical carcinogens are quite efficient in producing lung cancer in the hamster.

The Los Alamos people turned to plutonium-zirconium oxide microspheres, which could be made of exceptionally uniform particle size,^(b) even more uniform than the 3M microspheres. Also, ceramic zirconium oxide is chemically and biologically inert. The microspheres could be made in the laboratory (Anderson and Perrings 1978). The behavior of these, the excretion of plutonium so injected, survival, and pathological changes are given in progression by Anderson et al. (1974), Smith et al. (1976), Thomas and Smith (1979a), and in each Los Alamos annual report of the era. The negative results for life-span and biological changes, including tumorigenicity, continued so long as the number of microspheres per animal remained low enough to irradiate less than 20% of the lung mass.

If enough microspheres were crowded in to irradiate significant areas of the lung (i.e., over 20%), then lung tumor incidence began to rise. Also, intratracheal administration of a ^{210}Po solution à la Little brought incidences approaching 50%. This showed that there was nothing strangely different about the lung cancer susceptibility of the hamsters used in the Los Alamos experiments. An excellent summary table of the entire Los Alamos hot particle effort (except inhalation experiments) is given in the 1977 Los Alamos Annual Report (Anderson et al. 1978) and in ICRP Publication 31.

When the Pu-ZrO_2 was given as aerosol particles by inhalation, either in addition to or instead of injection, doses that had produced little or no effect when delivered by the entrapped microspheres produced shortening of life span, pulmonary neoplasms, and nonneoplastic pulmonary lesions (Thomas and

(a) There was a series of papers in *Health Physics* from Richmond's group, all under the basic title, "Biological Response to Small Discrete Highly Radioactive Sources." The one in 1970 cited is more closely related to reactions of the lung.

(b) The radioactivity of a uniformly loaded microsphere varies as the cube of the radius. For example, a 9% variation in dose rate can result from only a 3% change in particle diameter.

Smith 1979b). The results of this inhalation work are shown in table 9.17A, B. The dosages and treatment patterns are given in table 9.18.

¹In non-tumor-bearing animals

Source: Modified slightly from Thomas and Smith 1979a.

Note: For dosages and sequences see Table 9.18.

It should not be said that there was absolutely no effect in the intravenous experiments. Bronchioadenomatoid lesions (BAL) appeared at low incidence, and two animals receiving two thousand microspheres with a lung burden of 0.84 nCi developed tumors. Yet, the group with the highest incidence of BAL, viz., 6% that received six thousand microspheres for a lung burden of 26 nCi, did not develop a single primary lung tumor (Smith et al. 1976). It appears that disturbances began, but they never went on to the extent seen with the more diffuse sources.

¹Estimated from long-term lung retention kinetics (alveolar burden). The two digits used in these numbers were determined from retention equations, but it is obvious from such techniques that rounding off is a sufficiently accurate accounting of the actual lung burdens (e.g., 87 nCi could as accurately be reported as 90 nCi).

²Group D received ⁵⁷Co labelled ZrO₂ and i.v. aerosol particles.

³Group F received unlabelled ZrO₂ aerosol particles.

Source: Reset from Thomas and Smith 1979a.

The conclusion from this Los Alamos work strongly favors the thesis that diffuse sources^(a) are considerably more effective than a fixed concentrated source.

The original NRDC report quoted as strong evidence favoring the hot particle hypothesis the work of both Cember and the NYU group on implanted sources. This is to a degree a non sequitur. The experiments involved very large doses, as we have seen. One interesting report of Cember's was not quoted. This was work comparing the efficiency of radiation from insufflated barium sulfate labeled with ³⁵S (see section IV) and external radiation from x rays. There was a wide range of doses. The endpoint was survival, not cancer induction. The x-ray effects were much larger for a given total dose. Cember concludes, "The dramatic results of the external pulmonary irradiation indicates the validity of the hypothesis that a spatial concentration of absorbed energy may be less hazardous than a more uniform distribution of the total amount of absorbed energy in a greater volume of tissue" (Cember, Watson, and Grucci 1956, p. 400).

Meanwhile, across the country at Harvard, Little and colleagues were adding interesting new information to that already reviewed in section IV. They administered ²¹⁰Po intratracheally to hamsters in a relatively soluble form (saline solution) and when carried on iron oxide particles, i.e., as a nonuniform "hot spot."

(a) With the understanding that "diffuse" is used in a relative sense. Probably none of the sources were really uniformly distributed.

With doses from 55 to 2,700 rad to whole lung, the tumor yields from the particulate sources were equal to or less than those from the "uniform" exposure.^(a) This experiment was done specifically in response to the hot particle problem (Little, Kennedy, and McGandy 1978). In the next year, the same laboratory concluded that dose rate had little influence on carcinogenicity in this system (Little and Kennedy 1979). The pathogenesis, possible cells of origin of the tumor, and mechanistic aspects were added to the study, but they do not pertain directly to our consideration here of hot particles.

In section IV, we presented the plan of the Inhalation Toxicology Research Institute's program with monodisperse aerosols of plutonium and reproduced a figure showing calculated dose relationships with particles of different levels of radioactivity. We elected to defer further consideration of this work to this section on hot particles because of its pertinence thereto.

The first experiment involves comparison of the results on inhalation^(b) of a monodisperse aerosol of $^{238}\text{PuO}_2$ of 1.5- μm aerodynamic diameter (AD) with one of 3.0- μm AD. There were some differences in retention kinetics; e.g., the retention half-times in lung were 650 days versus 440, in liver 130 days versus 140, and in skeleton 140 days versus 340 for 1.5- versus 3.0- μm AD particles, respectively. The differences reside largely in the handling of the material prior to 100 days. (These differences between particles only a factor of two apart in average diameter introduce another factor into any consideration of the long-term effects of different particle sizes, i.e., differences in tissue retention times.)

Nevertheless, the biological results to date in this Lovelace experiment do not indicate that the difference in particle size has influenced the incidence or the type of lesions seen. The work is still in progress with many animals still alive.

In a larger experiment with $^{239}\text{PuO}_2$, monodisperse particles of 0.75 μm , 1.5 μm , and 3.0 μm were inhaled. The results are somewhat less far along than the ^{238}Pu study but indicate comparable findings.

The differences between ^{238}Pu and ^{239}Pu on a microcurie basis have been suggested by some to be due possibly to the greater uniformity of dose distribution in the lungs for ^{238}Pu (Sanders, Craig, and Smith 1974).

Experiments in Lafuma's laboratory in France, using rats (e.g., Lafuma et al. 1974; Lafuma 1978), suggest that toxicity increases as the uniformity of the pulmonary distribution of the element increases. For example, ^{244}Cm was the most toxic and the most highly dispersed.

This can be illustrated by a report from the German Commission on Radiation Protection, which was requested to address the hot particle problem. The results were published in 1978 (Commission on Radiation Protection 1978). Their analysis includes most of the Russian and French work, as well as that from the United States and concludes that the more uniform doses are more hazardous. They show a "relative heterogeneity factor" and a "relative toxicity factor" for a number of actinides as derived by Lafuma. Each is relative to ^{244}Cm nitrate. There is an inverse relationship between the two as shown in table 9.19.

The toxicity factor is corrected for the different alpha-particle energies of the radionuclides involved. The range is not great, especially in comparison to the

(a) Little et al. call it uniform without quotes. I have added quotes since there were probably some particles present in both instances as polonium colloids. The iron oxide particles were, however, much larger and much less uniform than the polonium given in a saline solution (Little, Grossman, and O'Toole 1973).

(b) Note that much of the other work is not by inhalation.

TABLE 9.19. Relative Heterogeneity Factor (H) and Relative Toxicity (T) of Inhaled Actinide Compounds in Rats

Compound	H ^a	T ^a
²⁴⁴ Cm-Nitrate	1	1

enormous differences suggested by the hot particle hypothesis, but they are reasonably regular and, of course, in the opposite direction from the postulates of the hot particle proposition.

2. Theoretical and Computational Approach

Using the principles of microdosimetry, especially the characteristics of the alpha particle track, several theoretical (e.g., modeling) approaches have been made. Early among these was work from Los Alamos by Dean and Langham (1969) and models in the NAS-NRC 1961 (BEAR) report.^(a) The former predicted that there would be an optimal dose and/or dose rate for tumor induction. The NCRP report (NCRP 1975a) contained estimates of the number of cells traversed as a function of activity of ²³⁹PuO₂ particles or uniformly distributed sources and gives numbers of singly versus multiply traversed cells for the particular source. This in turn allows calculation of the "specific energy" deposited in a microscopic area. If one makes assumptions about number of cells that must be involved (and how) in carcinogenesis, predictions can be made about incidence as a function of particle size. (This was not done in the NCRP report itself, but was engaged in by some members of the committee.)

The Los Alamos people, in designing their experiments, calculated the activity and number of ²³⁹PuO₂ or ²³⁸PuO₂ particles as a function of geometric diameter and the number of particles needed to produce one maximum permissible lung burden of 16 nCi (Richmond 1975). It would take 5.4×10^4 particles of 1 μm in diameter, but 5.4×10^{10} particles of 0.01 μm diameter to reach 16 nCi of ²³⁹Pu in the lung. They also calculated the number of cells at risk for a static lung burden of 16 nCi at the different particle diameters. With particles as large as 1 μm , only about 0.03% of the lung mass (3.6×10^8 cells) is at risk, while for the same activity, viz., 16 nCi, about 30% of the lung mass (3×10^{11} cells) is at risk with the smaller particles. Thus, the larger the particle the lower the number of cells at risk, but the higher the activity per particle. Again, it would not be surprising if there were some tradeoffs and a point of greatest hazard. Until we know more about carcinogenesis, we can only conjecture.

(a) See chapter 16.

There are also calculations of particle movement and its effect on the micro-distribution of alpha energy (NCRP 1975a; ICRP 1980, p. 87).

Mayneord and Clarke (1976) in the United Kingdom examined the hot particle problem in terms of numbers of irradiated cells and doses received. They produced a very broad study, which included linear and nonlinear dose response functions and alpha, beta, and gamma activity in point sources compared to uniform irradiation. Using an entity for expectation of effect called "absolute expectation," they calculated that in a large number of instances the mean organ dose and the assumption of a linear nonthreshold response function give a good upper limit of the expectation predicted from many of the point source postulates. This work was backed up by a detailed mathematical investigation published in a report of the U.K. Central Electricity Generating Board.

Some of the testimony at the hearings called by EPA on the LMFBR contained models and calculations of the sort we have been looking at. Since they do not introduce anything new, they will not be reviewed here. However, the reader will find these hearings a rich source of concentrated information (in places, at least).

A very simple but seldom emphasized aspect of the problem concerns the method of expressing dose. The biological data from which we derive risk estimates or other expressions of cancer incidence have conventionally used doses calculated on the basis of large volumes, i.e., whole lung, bronchial epithelium, postulated most sensitive cells or tissues, etc. If we accept the hot particle hypothesis, the calculated doses associated with a given effect would be much higher. The effect of reducing the critical volume from an average to lung to only 0.1% of the lung mass reduces the apparent effectiveness of plutonium alpha particles by a factor of 1,000. This is shown in figure 9.37, taken from Stannard (1975).^(a)

FIGURE 9.37. Illustration of effect of change in assumed tissue volume on position of dose response curve for incidence of lung cancer. (Redrawn from Stannard 1975.)

(a) A modified form of this graph appeared in WASH-1320 (Bair, Richmond, and Wachholz 1974).

This simplistic exercise points up an important fact. Both sides of these relationships should be based on the same system. We should not use macrodosimetry for determining dose associated with incidence obtained from biological data and microdosimetry for predicting incidence associated with a dose. Only if it is clear that the original incidence data and the predicted effects data utilize the same system are we playing fair. It is not fair to mix the computational approaches in midstream.

Finally, in section G of ICRP Publication 31, the task group calculated the expected number of lethal lung cancers in the dog experiments using the data on plutonium in dogs and the NAS-NRC (1976) estimates of how many 0.07-pCi and also how many 0.6-pCi particles there would be in the pulmonary region of dogs receiving the doses given. (They are 1.3 million and 200,000, respectively.) Using the proposition that a 0.07-pCi hot particle has a 1/2,000 chance of producing lung cancer, there should have been 650 lethal lung cancers *per dog* during the 11.5-yr average life span after exposure, or 100 lethal lung cancers per dog if the critical activity of a hot particle were raised to 0.6 pCi. The average dog actually had 1.9 primary pulmonary cancers.

Commentary on the Hot Particle Controversy. There seems to be little theoretical or experimental justification for the hot particle proposition as originally enunciated or as modified. The risk factor was derived almost gratuitously. The specifics have not held up. In a sense, the strong reaction of the scientific community and of administration can be viewed as a costly blunder, which derailed other important work. As in the case of the uranium miners (see chapter 3), the data were essentially already in place to tell us the correct answer. However, few knew it was in place and few believed we had enough information. Indeed, we probably did not have enough for all purposes and never will until we have a complete theory of carcinogenesis. The net result has been some progress in pertinent research and more understanding of lung dosimetry. The loss in other realms is not so easy to write off. Only in the future can we expect to answer that question.

Both ICRP and NCRP have agreed on again and reiterated the validity of using whole organs or significant radiosensitive parts of organs in calculating dose from deposited radionuclides. Yet, the problem for lung is still not settled. We are still in a quandary over many aspects of lung dosimetry and need new research. At the 1982 meeting of the Radiation Research Society, there was a special workshop, in two sessions, on lung dosimetry. One paper, by D. R. Fisher (Battelle, Pacific Northwest Laboratories) was entitled "In Search of the Relevant Lung Dose." The round table discussion, chaired by P. E. Morrow, was entitled "What is the Relevant Lung Dose?" (Fisher 1983). Need we say more?

B. Tobacco Smoke

We have seen experiments and discussions involving tobacco smoke, especially cigarette smoke, in several different contexts. Because of interest in the subject and for the convenience of the reader, a short recapitulation and a few additional observations are brought together here around the problems of pulmonary radiotoxicology.

There are at least three distinct ways in which tobacco smoke has been linked to problems in this field:

1. as a co-carcinogen with a radioactive material

2. as influencing the clearance of radioactive dust from the respiratory system
3. as the primary cause of lung cancer by virtue of the natural radioactivity of tobacco.

We will consider each of these in turn.

In reviewing the uranium miner problem (chapter 3), we saw the repeated introduction of the role of cigarette smoking as a complicating factor, i.e., as a possible co-carcinogen. The oft-repeated statement that only uranium miners who smoked got lung cancer seems to have been negated in recent years. Nevertheless, the epidemiology is still complicated by the relatively small size of the nonsmoking miner group.

The cell type in sputum samples from miners developing lung cancer in recent years has appeared to be more like that seen in smokers developing lung cancer than in the older miner population. This has led some to consider that the new cancers appearing in the uranium miner group are linked only to smoking, not exposure to radon and daughters. The marked reductions in radon levels in the mines by increased ventilation over the last decade or more support this thought. On the other hand, the current experience in no way answers the question of the role cigarette smoking played in the earlier incidence figures. Nor do differences in the smoking habits of different populations clinch the idea. Other factors are different too in these populations.

The animal work at PNL in which cigarette smoke was added to radon and daughter products (see chapter 3, section VIII B-2) went in the opposite direction. The presence of cigarette smoke seemed to mitigate the effects of radon and daughters. The authors speculate that the smoke increased the thickness of the mucus layer and/or stimulated mucociliary clearance. The PNL work with smoking dogs concentrated more on lung clearance than influence on cancer incidence.

Albert et al. (1975) used the NYU technique of double tagging of aerosols (see section IV) to measure short-term effects of cigarette smoking on bronchial clearance in humans. They could establish a base-line clearance rate over several hours by measuring the rate of removal of an aerosol tagged with one radionuclide (e.g., ^{198}Au or $^{99\text{m}}\text{Tc}$). With the base line established, a second aerosol marked with the other tag could be inhaled and this followed quickly by the smoking of several cigarettes. The clearance of the second aerosol was then measured. They continued measurements up to 90% of the total clearance. With fifteen subjects, the smoking episode increased clearance rate by a factor of about two. The effect was consistent. However, the authors quote work from other laboratories that showed slowing of bronchial clearance in some cases, acceleration in others.

Further NYU work with the donkey showed slowing of clearance after more than fifteen cigarettes.

Examination of the chronic effects of smoking has tended toward finding slowed clearance rates.

Many years before the NYU work, Bair and Dilley (1967) at Hanford found no influence of cigarette smoke on clearance of $^{59}\text{Fe}_2\text{O}_3$ or $^{51}\text{Cr}_2\text{O}_3$ particles from the lungs of rats. These were acute exposures. The same results appeared in dogs that smoked twenty cigarettes per day for five days per week for over a year. In later work on plutonium clearance quoted earlier in this chapter (section IV, part A 4 d), chronic cigarette smoking reduced clearance in both rats and dogs.

Further perusal of the subject indicates that, in the long term, there are decreases in clearance rates and thus longer retention of and higher doses from radioactive particles. The acute effects seem to be dependent not only on the dose of the smoke but on other factors, since different responses are seen in different subjects, even in the same experiment.

The possible role of the ^{210}Po in tobacco smoke as the causative agent in producing lung cancer in smokers was reviewed in chapter 4 (section V C). The results have been disparate, probably partly because of differences in the amount of polonium in different samples of tobacco, partly differences in the host response. Martell has been the most verbal champion of radioactivity as the causative agent. He seems to be willing to discount the experiments with negative results. It is interesting to note that Little and his associates conclude that the results in toto tend to support the hypothesis that ^{210}Po or ^{210}Pb in cigarette smoke may be a significant factor in the initiation of lung cancer in humans. (They point out that the radioactivity could easily be removed from tobacco without affecting flavor. However, this suggestion seems not to have resulted in any action by either industry or government.)

On balance, we must conclude as we did in chapter 4 that the highest concentrations of radioactivity found in tobacco might well be sufficient to initiate cancer, even without co-factors, while the lowest concentrations would have to be considered unlikely causative agents in themselves. The problem will not go away since it requires definitive answers to fundamental questions. A recent resurrection of the discussion comes from a 1982 letter from a group at the University of Massachusetts Medical Center published in the *New England Journal of Medicine* (Winters and Di Franze 1982). These authors bring to bear the fact that alpha particle ranges are short and average dose to lung is not a proper expression for the significant dose. They suggest that "The ^{210}Po alpha activity of cigarette smoke may be a very effective carcinogen if a multiple mutation mechanism is involved" (p. 365). Thus, features of the hot particle proposition appear in the context of production of lung cancer from cigarette smoke. The validity can be neither confirmed nor denied until the mechanisms are more fully worked out. Someday they will be. Meanwhile we can expect controversy.

C. SNAP, ROVER, Kiwi, NERVA

At the opening of the first large symposium on inhalation problems with radioactive materials (the Hanford symposium on Inhaled Radioactive Particles and Gases), Dr. William Lotz from the Division of Biology and Medicine of the AEC delivered a "Statement on the Problem" (Lotz 1964). He described urgent practical problems that required attention from inhalation toxicologists and aerosol experts. He exhorted his listeners to consider experimental work with a bearing on the practical problems of (1) the thermal energy devices using radioisotopes for the generation of electricity in space and at remote locations (SNAP—Systems for Nuclear Auxiliary Power); (2) Nuclear rocket propulsion (ROVER); and (3) the experimental reactor (Kiwi)^(a) to be used for development of nuclear rocket engines (NERVA).^(b) Related to these was the idea of a

(a) Kiwi seems not to be an acronym but to refer to the real bird which cannot fly. How did those who coined the name know it would never fly?

(b) Nuclear Engine for Rocket Vehicle Application.

nuclear-powered airplane. These problems were, of course, "special" and in addition to those of more routine operations.

1. SNAP

This is the only program of those above that went through development and became operational. Today there are many thermoelectric generators on satellites now in orbit, on the moon, and in remote areas of the world that obtain their heat from the presence of large quantities of radioisotopes. The first such source contained ^{210}Po and was demonstrated personally by President Eisenhower by having it light a small electric bulb on his desk. Later ^{90}Sr was used, but the alpha emitters have the advantage of requiring less shielding. Lotz (1964) lists eighteen materials used or proposed for SNAP devices. However, the choices gradually narrowed down, and ^{238}Pu became and is the most common material used. There is no question but the very considerable increase in demand for ^{238}Pu resulting from this choice led to much of the experimental work with this isotope we have already reviewed.

There were two major safety concerns with these devices in the minds of the biologists: mishaps during the early phases of launch, which would bring the device violently back to earth; and uncontrolled orbital decay and atmospheric re-entry. The engineers took care of the first problem by exceedingly sturdy construction, which withstood the most severe tests without breaching the source container. By contrast, it was determined that controlled re-entry from orbit could not be guaranteed and that the design should assure complete burn-up of the fuel core in the upper atmosphere. This decision was not satisfactory to the biologists.

These decisions were not reached overnight. There was a SNAP Hazards Safety Committee of the AEC, which weighed the alternatives diligently. Health hazards played an important role. Many meetings were held under the aegis of the Division of Biology and Medicine (DBM). The results of two of these were kindly made available to me by Dr. H. D. Bruner, who had much of the responsibility at Headquarters.^(a) The members were, in addition to Dr. Bruner, Roy Albert (NYU), William Bair (Hanford), Birney Fish (ORNL), Wright Langham (Los Alamos), Thomas Mercer (Rochester), Roger McClellan (Lovelace), Arthur Tamplin (Livermore), and William Lotz (DBM/USAEC). It was soon decided that gastrointestinal absorption was very low, and the protection of the cornified epidermal layers in the skin was sufficient to eliminate surface deposition and ingestion as important health problems. Inhalation and effects on lung were considered the major concern, although thought was given to gonads to the extent of careful calculations of how much the maximum possible amount from SNAP devices might add to the plutonium already accumulated from weapons testing fallout. It was considered not sufficient to make much difference biologically.

Obviously, particle size was an important parameter in estimating the inhalation hazard from a re-entry burn-up of a SNAP device. Many of the ideas that later triggered the hot particle issue came up for full discussion at the committee's meetings. It was agreed that full burn-up could probably result in a predominance of very small particles (i.e., it would be a fume). Thus, hot particles

(a) He is now at Bonita Springs, Florida. Dr. Bruner's reminiscences on a taped interview were also extremely helpful (Bruner 1979).

would not be present initially but might form later, either by coalescence in the atmosphere or in the lung. There was also consideration of the size of the populations potentially exposed and of what guidance should be given to agencies concerned in the event of a mishap.

An opportunity to test the calculations came unexpectedly. On April 21, 1964, a navigational satellite carrying a SNAP Device (SNAP 9-A) containing 17 kilocuries of ^{238}Pu (about 1 kg) failed to reach full orbital flight. The payload reentered the atmosphere in the Southern Hemisphere and burned completely. Long-term balloon and aircraft sampling and integrated fallout figures determined from samples of soil collected at sixty sites worldwide are discussed in detail by Hardy, Krey, and Volchok (1972). About 13 kilocuries could be accounted for, most of it in very small particle sizes, which remained aloft for years (residence half-time, fourteen months). The distribution, while localized in the Southern Hemisphere to begin with, gradually became worldwide, although it never became uniform. Because of the enormous dilution, no inhalation or other health hazards could be identified. Nevertheless, we must remember that none of the larger particles could have still been aloft by the time the sampling program got under way. We must assume that either there were very few or none of these, or that they fell in areas where they would not be detected (which was nearly everywhere in the area involved in the abort).

The health hazards associated with SNAP devices were probably as thoroughly discussed as any nuclear energy undertaking in proportion to their importance. So far, it appears that the planning and performance have been adequate. Even the one abort seems to have added only to the inventory of plutonium, not to discernible health effects.

2. ROVER, Kiwi, and NERVA

The possibility of developing nuclear-propelled rockets was a joint project of the AEC and the National Aeronautics and Space Administration. The Los Alamos Laboratory took a key role in developing the reactor technology and its adaptation to rocket engines. There was a prototype built for static testing in a remote area of the Nevada Test Site. There was also the idea that a modified reactor could propel an airplane if an airframe could be found that would separate the reactor and the crew by a suitable distance and still be airworthy. Neither device ever flew; the rocket primarily because of potential contamination problems, the airplane for the same reason, plus engineering problems.

There was an AEC Aerospace Nuclear Safety Committee with the same responsibilities (and I presume similar membership) as the SNAP Hazards Committee. The fuel elements of the experimental reactor contained about 10^{12} particles of ^{235}U carbide ($^{235}\text{UC}_2$) of about 100 to 200 μm in diameter (Dean and Langham 1969). Evidently it was expected that the rocket exhaust might contain some of these particles, but the chief concern was re-entry or failure to obtain orbit. It was very difficult to design a reactor core that could both produce a suitable thrust (e.g., by heating hydrogen) and be proof against rupture on impact. Certification that it would remain intact in an abort was not forthcoming. The particles would have undergone as many as 10^{13} fissions and have dose rates of 10^8 rad/hr at thirty minutes after reactor shutdown. These would indeed be hot particles!

The safety analysis in this case concerned both the hazard to skin, should even one such particle deposit on it, and the usual inhalation hazards. Their large size mitigated against their inhalation unless they broke up. Nevertheless,

some of Sanders's work at Hanford, already cited, left open the possibility of deposit of such particles in the upper respiratory tract. These workers urged experimental work by intratracheal instillation or surgical implantation to check on the effects produced by particles in the 100- to 300- μm range.

This author remembers meetings at which it was insisted that any nuclear rocket would have to blast off to at least orbital distance with chemical propellants. The nuclear power thrust, while lower, could last longer and get a payload on its way to interplanetary space if desired, but it could not be used in the earth's atmosphere. It has not been possible to find documentary proof, but it is this author's impression that the potential health hazards, both to skin and by inhalation, tipped the scales toward abandoning the project.

D. Organizational Considerations

Obviously, an effort as large as the work on inhalation of radioactive substances did not happen spontaneously. The bulk of the financing in the United States came through the AEC and its successors, the ERDA, DOE, and also the U.S. Air Force. The Department of Health, Education and Welfare was the second most active sponsor, particularly around problems of uranium miners and uranium mill tailings. Toward the end of the period of our interest, the EPA took over some functions and their financing, but not very much laboratory research. The Headquarters staff and AEC had major responsibilities for translating operational problems into research projects that would both attack the immediate problem and contribute to the ongoing acquisition of useful and meaningful knowledge. They were constantly evaluating progress, defending the need for and allocating funds, and promoting and coordinating the efforts of the several groups. Their role was a significant one to both the research and to the protection of the continuity of the effort, especially in long-term experiments.

An early planning session of significance and a good example of the role of the Headquarters Staff is seen in a 1961 meeting on the subject, "What Constitutes Respirable Dust?" The meeting was held at Los Alamos in January 1961. There were three university scientists, six participants from AEC contractor laboratories, three people from license compliance offices in the field, and six from various divisions at Headquarters. Two of the Headquarters staff were from Licensing and Regulation, two from Health and Safety, and one each from the Office of the General Counsel, and the Division of Compliance. The deliberations were made available to me by Dr. Donald M. Ross (Ross 1962, 1980), for many years Chief of the Health Protection Branch and a competent industrial hygienist.

With careful review of the literature, a decision was made to consider 10 μm the nominal upper limit for respirable dust if deposition in the nonciliated portion of the lung is implied. The concepts of respirable dust and selective sampling^(a), along the lines published later by Morrow (1964), and the decision to develop size-selective sampling devices were highlighted by this meeting. Furthermore, the fact that by "size" is meant an aerodynamic diameter with properties equivalent to a unit density sphere was emphasized. For many of the substances of interest to the AEC, this makes considerable difference. Table 9.20 illustrates this point vividly.

(a) As applied to insoluble particles.

TABLE 9.20. Equivalent Particle Diameters for Various Densities Compared with Unit Density

Material Density	H ₂ O 1.0	SiO ₂ 2.6	Yellow Cake 5.4	U ₃ O ₈ 8.4	UO ₂ 10.9
Diameter (in μ)	0.5	0.31	0.22	0.17	0.15
	1.0	0.62	0.43	0.35	0.31
	2.0	1.24	0.86	0.69	0.62
	3.0	1.86	1.29	1.03	0.92
	4.0	2.48	1.72	1.38	1.23
	5.0	3.10	2.15	1.73	1.54

	10.0	6.20	4.30	3.45	3.08

Source: Reset from Hyatt 1960.

Even though taken from the accumulation of wisdom among the participants and from previously published work, it seems likely that a meeting and report of this type helped much to bring important concepts out of the confines of specialized areas.^(a)

Another useful type of coordination, which went above and beyond the budget submission and approval process, is exemplified in the Inhalation Toxicology Working Group managed largely by W. E. Lotz at Headquarters with encouragement and help from H. D. Bruner. We have already glimpsed the value of its operation in bringing people from the cognizant laboratories together for reviews of specific programs.

The general review of plutonium work nationwide in the early and mid-1970s by a series of Task Forces responsive to a Plutonium Committee of AEC was discussed in chapter 8. Much of the material in this review concerned inhalation studies. Likewise, a considerable portion of the 1977 Actinide Workshop at Seattle, described in chapter 8, concerned inhalation experiments under way and their responsiveness to the needs of the time.

When the AEC was about to be transmuted to ERDA, there was a thorough review of not only all work under way in the radioactive inhalation field, but postulates for new work in the inhalation toxicology of all forms of energy generation. An excerpt from the in-house document reviewing the problems and plans is given below.

The declaration by Congress on October 8, 1974 . . . to accelerate . . . development of all energy sources to meet the needs of present and future generations, and to make the nation self-sufficient in energy, also directed that public health and safety be concomitantly assured. The generation of new toxic aerosols by rapidly developing energy sources, superposed upon those agents presently responsible for an alarming increase in lung cancer in the general population and severely increased

(a) Remember that the numerous helpful reviews we have mentioned were not published yet.

chronic respiratory disease in industry, could rapidly magnify the danger of widespread disease caused by inhaled airborne contaminants. This will occur unless a comprehensive program is promptly implemented to define the nature, properties, environmental levels, and biological disposition of these airborne toxicants, as well as mechanisms of pulmonary or systemic disease caused by aerosolization of energy-related materials. Such a program must incorporate 1) identification of inhalation hazards and characterization of their sources, 2) studies of physical-chemical characteristics of air-borne particulates and gases that affect their physical and biological behavior, 3) evaluation of factors and processes that affect respiratory tract deposition and retention, 4) increased understanding of mechanisms, pathways, and kinetics of biological disposition of deposited agents, including cell-mediated and dissolutive clearance, translocation rates and fractions, and processes of elimination or detoxification, 5) identification of the nature and degree of deleterious effects, both acute and delayed, resulting from inhalation of toxic materials arising from, or related to nascent energy technologies, 6) establishment of primary and sequential dose-effect relationships, 7) identification of sensitive populations and studies of the influence of age or compounding diseases upon effects, 8) predictive models based upon experimental work, 9) evaluation of effects of localized concentrations vs. diffuse distributions of inhaled contaminants in critical tissues, 10) mechanisms of repair and recovery. (ERDA 1975)

This was followed by a detailed consideration of priorities for research in each of the named areas.

What broader or more comprehensive template could we need to judge our plans and the progress of our research in this field? What better way to conclude this chapter but to suggest that our progress and the unanswered questions remaining be reviewed against this template? If we as a nation fail to achieve our comprehensive research goals in inhalation toxicology, it cannot be attributed to inadequate planning at the scientific level in government, which continues to be the most likely single source of support for this important work.

VI. Summary and Commentary

As in most industrial environments, the primary route of entry of radioactive materials into the body was expected to be by inhalation of vapors, dusts, particles, or gases. This chapter considers the enormous efforts expended on inhalation of dust and particles. Chapter 10 considers radioactive gases and vapors.

There was a considerable effort during the years of World War II devoted to inhalation problems. There was an industrial hygiene air sampling program, both personal and area monitoring, and large experimental programs with animals to determine the behavior and effects of inhaled radioactive materials. The largest from the standpoint of both industrial measurements and experimental work concerned natural uranium. The bulk of these experiments on inhalation toxicology of uranium took place at the University of Rochester, and their discussion occupies considerable space in the chapter. Important adjuncts to this work included the development of aerosol science, particularly the role of particle size and the characterization of inhaled dusts. Since natural uranium is weakly radioactive, exposure methodologies did not need to be markedly different from those used for investigation of nonradioactive dusts.

Work at Berkeley and Chicago during World War II delved more into the inhalation of aerosols of more highly radioactive materials. In addition to rather crude burning wire procedures, several inhalation experiments were carried out using the off-gases from the Clinton "Pile," under the auspices of both Berkeley

and Chicago. There was, in addition, a small program at Rochester in which ^{210}Po aerosols were produced by volatilization from a heated wire and inhaled by rats.

In addition to enhancing greatly our knowledge of the role of particle size, these early experiments demonstrated that insoluble complexes of the inhaled radioactive materials were frequently formed and remained in the lung. This could occur even when the initial form was expected to be "soluble."

In the decades of the 1950s–1980s, the entire field of inhalation studies expanded greatly. Chicago and Berkeley cleaned up some tag ends from the war years. Rochester continued as a center for inhalation studies by developing special facilities, carrying forward the eleven-year study of uranium described in chapter 2, and by including this field in its extensive educational program. Indeed, it produced many of the individuals who went on to develop or take key roles in other inhalation programs.

Hanford began in the field in early 1950 using intratracheal instillation and was the first to demonstrate the production of a lung tumor by plutonium. Under the direction of W. J. Bair, Hanford (now Battelle, Pacific Northwest Laboratories) has become a major center for all aspects of the inhalation toxicology of radioactive materials. While primary emphasis was on plutonium and the actinides and on radon problems (as we saw in chapter 3), many other groups of radionuclides were investigated. The rather remarkable ability of plutonium to produce lung cancer forced experiments to lower and lower levels of exposure. Naturally, one does not produce dangerous aerosols of highly radioactive materials without special facilities and equipment. The Hanford program produced many original designs. Some of these are depicted in the chapter. They were noted for ability to add adjuvants, such as cigarette smoke, mine air dust, etc.

In the 1960s, a new center was built near Albuquerque, New Mexico, to attack the problem of inhaled fission products. This was managed by the Lovelace Foundation, originally directed by Randolph Lovelace and C. S. White. It later became the Inhalation Toxicology Research Institute and is under the direction of R. O. McClellan. Since many of the fission products are beta or beta-gamma emitters and thus produce more penetrating radiations than the alpha emitters emphasized at Rochester, and, in part, at Battelle, still more refinements of methodology were needed. The development of the facility is described in chapter 8, but the results appear in this chapter. The ITRI group did much of their work with an insoluble carrier aerosol as a vector in order to separate out contrasts in effects due to differences in radionuclides from those due to differences in aerosols. They also developed a reproducible monodisperse aerosol.

The group at New York University carried forward on a broad front. They had much connection with the analyses of industrial exposures, partly themselves and partly by collaboration with the AEC office of Health and Safety that was directed for many years by Merrill Eisenbud, who later spearheaded the radioactivity work at NYU.

There was also activity concerning inhalation of radioactive aerosols at Harvard (Little et al.), Pittsburgh (Cember), Cincinnati (Cember), Wayne State University (Vorwald), and the Naval Radiological Defense Laboratory (Cohn), and others.

In the early 1970s, the inhalation field was shaken by the "hot particle problem." This resulted from allegations by the Natural Resources Defense Council of Washington, D.C. that discrete, highly radioactive particles, either inhaled or formed in the lung, were much more likely to produce lung cancer than the

same radiation dose spread over a larger area. Nearly every laboratory diverted some of its attention to investigating these allegations. It was probably Los Alamos that was drawn in in the most *de novo* fashion. At Los Alamos, an extensive program was developed with microspheres (Richmond et al.). These uniformly-sized plastic spheres could be coated with various amounts of radio-nuclides (e.g., plutonium), injected, and, because their size was just right, lodged in the capillaries of the lung. They thus acted as a realistic surrogate for a "hot particle." In addition to the flurry of experimental work, several expert committees were convened on both sides of the Atlantic to address the problem. The results to date have confirmed the conclusions that could be drawn by sophisticated intuition, viz., that there is greater cell killing around the "hot particle" and that, in terms of carcinogenic potential, a diffuse source may be just as, if not more, dangerous in causing cancerous changes in cells.

There were also inhalation programs around special nuclear devices and the possibility of a one-point detonation of a nuclear device. These are described briefly in the chapter, but the results are reserved for chapter 14.

It is commonly stated that the enormous effort surrounding problems of the inhalation of radioactive materials led the way over the last decades for all of inhalation toxicology. This is true and surprising in view of the fact that technically the problems were difficult indeed. We must be thankful for the relative generosity and especially the steadfast reliability of the sponsoring agencies that allowed the work to progress logically. It is ill-suited to a small academic enterprise. The results have demonstrated that there can be no substitute for an actual inhalation experiment in approaching either a practical understanding of the behavior and effects of specific substances or the underlying physiology, pharmacology, and pathology of the respiratory system.
